Australian chats are small, largely insectivorous terrestrial passerines endemic to Australia. Their relationships have been discussed by various authors, and they have in the past been placed with the thornbills in the family Acanthizidae. The majority of modern taxonomists, however, consider them to be close to the honeyeaters (Meliphagidae). Indeed, many current workers place the Australian chats in Meliphagidae, within which some consider them to form a subfamily, Epthianurinae. A number of other taxonomists have preferred to recognize the morphological and physiological adaptations of Australian chats to arid and semi-arid environments, and have therefore followed earlier treatments in considering them a distinct family, Epthianuridae. This last treatment does at least have the advantage of drawing greater attention to these rather interesting birds.

As presently treated, the family Epthianuridae comprises five species in two genera, *Epthianura* and *Ashbyia*. The Crimson Chat (*Epthianura tricolor*) and the Orange Chat (*Epthianura aurifrons*) occur mostly in arid and semi-arid regions of central and southern Australia, and the Yellow Chat (*Epthianura crocea*) is found at scattered sites in tropical northern Australia and arid regions of central Australia. The White-fronted Chat (*Epthianura albifrons*) inhabits various zones across southern Australia and is the only member of the family present in Tasmania. The Gibberbird (*Ashbyia lovensis*) occurs only in arid central Australia.

Despite the English vernacular name, the Australian chats are not related to the Old World chats of the tribe Saxicolini, which are part of the thrush family (Turdidae). The term "chat" may be an allusion to the epthianurids' ground-dwelling habits and rather robust body, which are not unlike those of such saxicolines as the wheatears (*Oenanthe*). Other common names often applied to various species include "nun", "tang", which probably refers to the call given by some members of the family, and "canary", which is presumably a reflection of the bright red or orange colours of the Crimson and Orange Chats).

Close affinities between the Australian chats and the honeyeaters were first suggested by morphological studies, particularly observations by S. A. Parker which confirmed that both groups had a brush-tipped tongue. Analysis of egg-white proteins appeared to support such a relationship. Studies by C. G. Sibley and J. E. Ahlquist, using DNA-DNA hybridization, added further support to the theory that Australian chats are in fact honeyeaters, and this was later corroborated by L. Christidis and

R. Schodde, who analysed allozyme (protein) variation. A more recent study, involving the sequencing of mitochondrial and nuclear DNA, has provided additional compelling evidence to show that Australian chats are nested deep within the family Meliphagidae. The DNA-sequence data indicate that the Australian chats form one of three separate groups within a poorly resolved clade. The second group comprises the largely northern Australian honeyeater genera *Conopophila* and *Ramsayornis*, and the third group consists of the New Guinean endemic genera *Melilestes*, *Melipotes* and *Timeliopsis*. Unfortunately, the DNA data shed little light on the evolutionary and phylogenetic relationships among these three groups.

The five species of Australian chat are endemic to Australia. Sometimes placed with the thornbills in Acanthizidae, there is growing consensus that they are most closely related to honeyeaters (Meliphagidae). This link is corroborated by studies of egg-white protein, DNA and allozymes, as well as shared morphological features, including a brush-tipped tongue, though this is vestigial in the chats. Males tend to be strikingly patterned or brightly coloured. In summer plumage, for example, the male **Yellow Chat** is vivid yellow with black lores and a distinctive black crescent on the upper breast.

[*Epthianura crocea crocea*, Roebuck Plains, Western Australia, Australia.  
Photo: Ian Montgomery]

Australian chats are small semi-terrestrial passerines with relatively long legs and an upright stance. In this regard they are vaguely reminiscent of wheatears (*Oenanthe*). All five species occur in open or lightly wooded country, where they are seen mainly on the ground, walking jerkily, or in low bushes. They are all well adapted to arid environments, particularly the **Gibberbird**, which lives in some of the driest regions of Australia. It typically inhabits stony gibber plains with a sparse cover of saltbush (*Atriplex*) and other low shrubs, grasses and herbs. Unlike most Australian chats, it is quite difficult to find because of its cryptic coloration.

[*Ashbyia lovensis*,  
Birdsville District,  
Australia.

Photo: Ian Montgomery]

Most taxonomic lists place the Australian chats at the end of the honeyeaters, starting with the Crimson Chat. Some authors consider the Crimson Chat to be most closely related to honeyeaters on the basis of external morphology, and the recent genetic data largely support this hypothesis. The sequence usually continues with the Orange, Yellow and White-fronted Chats, followed by the Gibberbird. Most treatments recognize only two epthianurid genera, *Epthianura* and *Ashbyia*. Some authors suggest that three subgenera exist within *Epthianura*, the differences lying mainly in colour patterns; thus, the Crimson Chat is sometimes included within the subgenus *Parepthianura*, the Orange and Yellow Chats in *Aurepthianura* and the White-fronted Chat in *Epthianura*. The data derived from analysis of mitochondrial and nuclear DNA, however, indicate that the Crimson and Yellow Chats are, in fact, more closely related to each other than either is to the White-fronted and Orange Chats. It is interesting that the first two have distinct breeding and non-breeding plumages, whereas the White-fronted Chat, the Gibberbird and, from the available evidence, the Orange Chat do not. All five species exhibit sexual plumage dimorphism, but in the case of the Gibberbird this is subtle. Seasonal, sexual and age-related variation in plumage is discussed further below (see Morphological Aspects). There are also closer vocal similarities between the Crimson Chat and the Yellow Chat when compared with the Orange and White-fronted Chats (see Voice). The DNA data indicate that the Gibberbird lies outside these groups, thus supporting the recognition of a separate genus, *Ashbyia*. There is no evidence to suggest that any of the species of Australian chat hybridize with one another.

The fossil record provides no information concerning the evolution and ancestry of the Epthianuridae. The molecular data mentioned above, however, do shed some light on the evolution of honeyeaters. The DNA-sequencing studies undertaken by A. C. Driskell and L. Christidis suggest that the honeyeaters arose during the mid-Tertiary, when heathlands were widespread in Australia. The largely arid-adapted Australian chats probably arose after this time, when rainfall patterns changed and heathlands became more fragmented, and they are part of a genetic clade comprising Australian endemic honeyeaters *Conopophila* and *Ramsayornis* (which occur mainly in mangrove and watered habitats) and New Guinean highland species. There is little molecular evidence for the evolution of separate endemic Australian and New Guinean honeyeater radiations. Further work is needed in order to ascertain the origins of Australian chats and their relationships with other Australian and New Guinean endemic honeyeaters.

Australian chats share many features, particularly skeletal characteristics, with the Meliphagidae. These include the slender head and decurved bill, the slender and attenuate palate, small temporal fossae, fully perforate nares and a single, deep fossa at the head of the humerus. There are, however, significant differences between Australian chats and meliphagids in cranial anatomy, the former possessing thinner nasal bars, smaller, thinner ectethmoid foramina and flimsier terete maxillo-palatine processes. Australian chats differ further from honeyeaters in having only a vestigial brush tip on the tongue. Certain epthianurid species have bright yellow, red or orange plumage coloration, which renders them distinct from Australian honeyeater species with the exception of largely tropical and subtropical genera, such as *Myzomela*.

Four of the five members of the present family display no apparent geographical variation. There are several subpopulations of the Yellow Chat and three subspecies are recognized, these being distinguished mainly by slight differences in the breeding plumage of the adult males. Otherwise, the White-fronted Chat exhibits slight morphometric differences between populations in Tasmania and those in mainland Australia, the former having a longer average bill length compared with mainland individuals. This is probably a result of their geographical separation at times over the past 12,000 years and the effect of the Bass Strait as a barrier to gene flow.

### Morphological Aspects

Epthianurids are small terrestrial passerines which are largely adapted to arid and semi-arid environments in Australia. They present only slight variation in size, the Gibberbird being on average the largest species, 11–14 cm long and weighing 14–20 g, and the Yellow Chat on average the smallest, with a length of 11–12 cm and a weight of 7–10 g. There is evidence that individual weight varies throughout the day, as indicated by studies of the White-fronted Chat, ringed individuals of which weighed on average 1.1 g less at dawn compared with later in the day. In addition, the weight of this species was found to vary seasonally, White-fronted Chats tending to be heavier in spring than at other times of the year.

Australian chats are structurally similar to honeyeaters. They have rather a rotund body, more so than that of most honeyeaters, and they have fairly short, broad and rounded wings with ten primaries. The third and fourth outermost primaries are the longest, as opposed to usually the fourth and fifth in the Meliphagidae.

There are nine fully developed secondaries, including three tertials, and at least some species have a vestigial tenth, innermost, secondary. The secondaries have rather distinct emarginations on the outer webs. The alula and outer primaries of juvenile chats are more rounded than are those of adults. The ephthianurid tail is rather short, with a squarish or slightly rounded tip when folded; it contains twelve rectrices, the outermost of which is typically the longest. The bill is short and slender, and typically straight, although that of the Crimson Chat is slightly more decurved compared with the bills of the four other species. The nasal groove is elongated, occupying up to a third of the exposed culmen. The legs are fairly long and fine, and the feet are rather weak, with the middle toe the longest, the Yellow Chat's middle toe being comparatively longer than that of the other species. The tarsus is laterally compressed, scutellated at the front and smooth at the rear. Compared with the chats in the genus *Ephthianura*, the Gibberbird differs slightly in that it has a thicker bill and a slightly broader and shorter trans-palatine process.

The plumage is dense and, in the case of adult males, brightly coloured or patterned. In the Crimson Chat, and possibly other species, the feathers of the crown are erectile and can be puffed up in territorial or courtship displays (see Breeding). Plumage patterns vary within the family, adults of most species showing obvious sexual dimorphism, but the Gibberbird exhibits only slight plumage differences between the sexes. First immatures of the Crimson and Yellow Chats are sexually dimorphic in plumage. Juvenile plumage is superficially similar in colour to that of the adult female, but the feathers, particularly on the hindneck, mantle and rump, and sometimes on the uppertail-coverts, are softer and more loosely textured than those of first immatures and adults. This is due to the lower density of barbs in juvenile feathers compared with those of adults. Juvenile tail feathers are narrower and more pointed at their tips than those of adults, and the juvenile primaries, particularly the outer primaries, and alula feathers are slightly broader and more rounded at their tips. These differences in feather shape between juveniles and adults are similar to those found in many genera of honeyeaters.

Post-juvenile moult, also termed first pre-basic moult, probably starts within 2–3 months after the bird has hatched, and involves all or most feathers of the head and body and most of the wing-coverts. Most individuals retain at least some of the rectrices, outer secondaries, inner primaries, alula feathers, and greater primary and secondary upperwing-coverts. With the sole exception of the White-fronted Chat, the post-juvenile moult results in a first-immature plumage resembling that of the adult female of the species. In the case of the White-fronted Chat, the first immature is superficially similar to the adult of the corresponding sex; first-immature male White-fronted Chats show a distinct contrast between the retained juvenile upperwing feathers and the adult-like feathers replaced in the post-juvenile moult. With Crimson and Yellow Chats, first-immature males are usually more brightly coloured than are females of the same age. At least some of these young male Yellow Chats have a few blackish blotches on the breast, and a few individuals have a narrow blackish crescent similar to that of adult males. First-immature male Crimson Chats usually have richer red feathering on the crown and uppertail-coverts than do first-immature females, but they are not so richly coloured as are adult males. The adult plumage is probably acquired at about one year of age, in a complete post-breeding, or second pre-basic, moult.

An interesting difference among the five species of Australian chat concerns seasonal variation in adult plumage. This difference is most pronounced in adult males. The available evidence indicates that adults of both Yellow and Crimson Chats possess different breeding and non-breeding plumages, resulting from separate pre-breeding and post-breeding moults. The post-breeding moult is complete, and typically occurs from mid-spring to autumn, although the timing of the moult of Yellow Chats is not understood. The pre-breeding moult is partial, involving most feathers of the head and body and some wing-coverts, and possibly also some rectrices. In comparison, the meliphagid honeyeaters do not have separate breeding and non-breeding plumages, although the Banded Honeyeater (*Certhionyx pectoralis*) is thought to be one of the few exceptions to this rule.

The timing of the post-breeding primary moult of the Crimson and Yellow Chats may relate to the nomadic movements made by these species (see Movements). The replacement of the remiges is not always conventional, and arrested or suspended primary moult appears to be commonplace. It is possible that the primary moult is suspended or arrested when breeding activity occurs. In the case of the Crimson Chat, the pre-breeding moult tends to take place from late spring to late summer, resulting in the non-breeding plumage in autumn and winter.

As mentioned above, the timing of the pre-breeding and post-breeding moults of the Yellow Chat is not understood. There is some evidence that the two moult cycles overlap to some extent, as is thought to occur with certain species of fairy-wren (*Malurus*) in Australia.

## Habitat

Australian chats typically occur in low shrublands or in vegetation surrounding lagoons, swamps, and estuarine or riparian habitats. They are well suited to arid environments, largely because of their physiological adaptation to water stress. Lightly wooded country and shrub-steppe, including open chenopod and samphire shrublands, are favoured by most members of the family. All five species are seen mainly on the ground or in the understorey, and are rarely recorded in the upper levels of trees.

The Gibberbird probably exhibits the greatest degree of habitat selectivity of all ephthianurids. This species lives in some of the most arid areas of Australia, typically on gibber plains, stony country with a sparse vegetative cover including Mitchell grass (*Astrelia*), saltbush (*Atriplex*), bluebush (*Maireana*), copper-burrs and bindyis (*Sclerolaena*) and other low shrubs and herbs. The Crimson and Orange Chats, too, occur in arid areas, but their ranges extend to semi-arid, temperate and occasionally subtropical environments, particularly during periods of inland drought. Crimson Chats are often found in mulga and riparian woodlands in central Australia, whereas Orange Chats tend to show a preference for low-growing shrublands such as samphire shrubland and low herblands or shrublands surrounding drainage lines and wetlands. The Yellow Chat typically occurs in vegetation associated with ephemeral or semi-permanent wetlands; its favoured habitats include lignum (*Muehlenbeckia*) or tall grasses, such as *Eragrostis* or *Sporobolus*, associated with freshwater or saline wetlands in inland and northern Australia. Occasionally Yellow Chats occur in chenopod and samphire habitats.

White-fronted Chats make use of a more extensive array of habitats compared with the other members of the family. The White-fronted Chat occurs in coastal shrublands, low samphire shrublands, vegetation surrounding freshwater wetlands, riverine areas, mallee heath, open woodland, open forest, and altered habitats such as golf courses and farmland. In mallee-heath habitats of south-eastern Australia, the White-fronted Chat is known to colonize recently burnt areas.

As suggested above, some species appear to adapt to a wider range of habitats when undergoing nomadic movements (see also Movements). Crimson and Orange Chats typically occur in arid habitats in inland Australia, but during drought periods in those regions these species move to subcoastal and even coastal environments. White-fronted and Yellow Chats may likewise undertake nomadic movements, but it is not understood if they make any associated changes in habitat selection.

The majority of the species occur in low-lying areas, typically from sea-level to elevations below 1000 m. White-fronted Chats are occasionally recorded at higher altitudes, as, for example, on the Southern Tablelands of south-eastern Australia.

## General Habits

Most Australian chats are frequently observed on the ground or atop shrubs and low bushes, particularly during the breeding period. They are typically easy to approach and are not especially wary of human observers, although they are more wary when nesting. The Gibberbird rarely, if ever, perches on the tops of

The most distinctive and widespread member of the family is the **Crimson Chat**. Like most of its congeners it is sexually dimorphic. The male is bright red on the cap, and much of the underparts, while the female is largely brown and whitish.

The crown feathers in this species, and possibly in other Australian chats, are erectile, and can be raised in display. Moults and seasonal variation are poorly understood in the family, but males of this species appear to undergo separate pre-breeding and post-breeding moults, resulting in different breeding and non-breeding plumages. The non-breeding plumage is significantly duller.

The bill of the Crimson Chat is short, slender, and blackish. The culmen is slightly more decurved than in other epthianurids, but like them it bears an elongated nasal groove for nearly a third of its exposed length.

[*Epthianura tricolor*.

Photo: Raoul Slater/Lochman Transparencies]

shrubs, but it has been recorded as perching on fence posts. Most members of the family are readily detected by sight and call, but the Gibberbird tends to be more cryptic, blending in with the substrate more effectively than do the other species. All species are diurnal in activity.

The majority of epthianurids allow fairly close approach by the observer. They are often observed while they are walking, not hopping, on the ground, when they have an upright stance and a rather jerky action. The flight of most is characteristically rather buoyant, jerky and undulating, and often fairly high. White-fronted Chats are often seen in flight overhead, when the distinctive "tang" calls alert the observer to their presence. White-fronted,

Crimson and Orange Chats often perch on the tops of taller shrubs and small trees, particularly during the breeding season when the adult males establish and advertise their territories. The Gibberbird, while perched on a stone or on the ground, often adopts a characteristic upright stance, frequently with the tail held in a lowered position, in a manner not unlike that of the Australasian Pipit (*Anthus novaeseelandiae*). Gibberbirds, however, often remain almost motionless when approached by the observer, and this behaviour appears to be distinct among the Australian chats. When flushed, Gibberbirds typically move in a rather strongly undulating flight, and they are known to use mammal burrows as refuges in which to evade the observer.

Australian chats eat insects, which they capture from bare ground, or occasionally from shrubs and small trees. The **White-fronted Chat**, a familiar species in many parts of Australia, is the best-known member of the family. It captures a wide range of adult and larval insects, including beetles, bees, butterflies, moths and grasshoppers. It also eats non-insect food, such as spiders, springtails, isopods, and occasionally small gastropods. This female is devouring typical prey—an insect larva—but the diet includes a small proportion of plant material, including seeds, nectar and fruit.

[*Epthianura albifrons*, Augusta, Western Australia, Australia.  
Photo: Ian Montgomery]

At the start of the breeding season, male Crimson Chats perform distinctive display-flights, either for territorial advertising or as part of the courtship ritual. The male flies on a steep angle from the top of a shrub or small tree to a height of more than 10 m, gives a territorial call, and then, folding the wings towards the body, descends back to a perch on top of a shrub. Courtship-flights are discussed in more detail later (see Breeding).

The adult males of most epthianurid species are brightly coloured and are conspicuous in the field. For example, the striking red uppertail-coverts of the Crimson Chat allow most observers immediately to detect and identify the species, even when it is only briefly glimpsed. Adult females, immatures and juveniles tend to be less conspicuous than adult males. The Orange, Crimson, Yellow and White-fronted Chats have fairly prominent calls, allowing for ready detection by the observer (see Voice). The Gibberbird, on the other hand, has somewhat weaker calls and is probably less readily detected by means of its voice. The distinctive injury-feigning "broken-wing" display of most species also alerts observers to the presence of the bird and a nearby nest (see Breeding). Male Crimson Chats have erectile crown feathers, and these are raised when the bird is advertising its territory (see Breeding).

Although most members of this family are recorded in pairs or small groups, they do sometimes form larger flocks. White-fronted, Crimson, Yellow and Orange Chats are occasionally observed in flocks containing 50 or more individuals. The Gibberbird, however, typically occurs in pairs or small parties, and is seldom seen in flocks of more than four or five birds. White-fronted, Orange and Crimson Chats tend to gather in flocks in the non-breeding season, but often live in pairs in the breeding season. Many of the larger flocks of Crimson Chats observed in the non-breeding season are thought to consist largely of immatures, but it is difficult to distinguish between immatures and adults in non-breeding plumage. More detailed information, including analysis of trapped individuals, is needed in order to ascertain the age and sex ratios in these flocks. At the start of the breeding season, some species, including the Crimson and White-fronted Chats, disperse in pairs. In the case of the White-fronted Chat, flock size is known to vary throughout the day, at least at some locations. At one site in southern Victoria, for example, flocks of this species, and also the proportion of the population contained within flocks, are larger just before sunset than they

are at midday. For the Yellow Chat and the Gibberbird, there is little information on seasonal or other changes in flock size, probably because these species occur mainly in remote areas of Australia and are seldom studied.

Flocks of White-fronted Chats will rise in the air and circle when predators such as the Brown Falcon (*Falco berigora*) or the Australian Kestrel (*Falco cenchroides*) are nearby. The flock-members keep in contact by calling to each other.

The roosting behaviour of the family is not well understood. White-fronted Chats roost communally, typically in low samphire shrubs, arriving in flocks in the evening. Incubating and brooding females of this species apparently roost in the shrub in which the nest is built. The Crimson Chat and the Orange Chat will also rest up and sleep in low shrubs during the heat of the day. There is no information available on the roosting habits of the Yellow Chat and the Gibberbird.

Preening behaviour is equally poorly documented. White-fronted Chats bathe in freshwater pools, and it is likely that the other members of the family do likewise. Crimson Chats have been recorded as sun-bathing and dust-bathing in captivity, but there are no known observations of such behaviour by epthianurids living in the wild. Again, it seems probable that this behaviour does occur but has yet to be seen by ornithologists.

## Voice

Australian chats have a fairly wide variety of calls, but, given the relatively common status of several of the species, surprisingly little is known about the vocalizations of the family. Typically, the calls are not particularly loud, but they are quite readily heard in the field and are often diagnostic. Most species have distinctive contact, advertising and display calls, given by individuals either when perched or when in flight.

Vocalizations vary from relatively simple notes to more complex songs, depending on the species. The majority of them utter a variety of sounds, including fairly high-pitched whistles and piping calls, churring and chattering notes, and metallic, nasal, buzzing and twittering sounds. One of the more interesting aspects of non-vocal sounds, at least of some species, is bill-clicking, which is performed in territorial display (see Breeding). The Crimson Chat has a broad repertoire of calls, which vary accord-

ing to behavioural activity. This species emits the full range of sounds mentioned above, including a sweet "wheee" whistle given one or more times in succession, a louder "tee wheee" call given in display-flight, short nasal or metallic single-note calls, harsher "jet jet" and short and soft "jut jut" notes, and faint twittering calls. This is one of the species which clicks its bill in display, but there are few details and no published sonagrams of the sounds produced by this action. Crimson Chats are said also to make a faint hissing sound in distraction display (see Breeding). The Yellow Chat apparently has a range of calls similar to that of the Crimson Chat. These include a high-pitched three-note whistle transliterated variously as "pu-li-pii" or "pli-pi-lii" and given at a pitch similar to that at which the whistles of the Crimson Chat are uttered, which is about 4 kHz. Yellow Chats are known to emit short harsh chirping or churring calls in distraction display, as well as short, nasal "tang" calls similar to those of most other members of the family.

The vocal repertoire of the Orange Chat is poorly known, but it includes nasal single-note "tang" calls, not unlike those made by White-fronted Chats, a fairly distinctive metallic rasping call with a pitch of up to 6 kHz, a soft "shu-shu" in distraction display, and weak songs given in display and from the tops of shrubs. The evidence strongly indicates that Orange Chats are not so vocal as are Crimson Chats and their calls are not so loud or diagnostic. In contrast, the White-fronted Chat has what is perhaps one of the most diagnostic calls of any species of Australian chat, this being a fairly loud nasal "tang" contact call given in flight or from atop a shrub. Indeed, one of the common colloquial names applied to this epthianurid is "Tang", a direct reflection of this call. The "tang" call is not unlike that uttered by the Zebra Finch (*Taeniopygia guttata*), and the latter species, a member of the family Estrildidae, is known to respond to calls made by White-fronted Chats. The White-fronted Chat is not known to sing obvious songs, or, at least, not to deliver such songs frequently, but it does produce chattering calls and bill-clicking sounds.

Although the voice of the Gibberbird is rather poorly known, this species does emit weak twittering and chattering notes, as well as plaintive piping and rapid whistling calls. The multiple-note piping calls of this species can descend or ascend slightly in pitch.

There appear to be only few examples of members of this family indulging in vocal choruses. Crimson Chats sometimes occur at rather high population density, particularly after good rains in the arid zone, and in these circumstances numerous individuals can be heard calling at one time. There is, however, no

evidence for antiphonal calling, or duetting, by Australian chats. The behavioural functions of epthianurid calls are not well understood. Distinctive whistling calls are given by males of such species as the Crimson and Yellow Chats in display-flight, and are typically uttered during the steep descent phase of the flight. Apart from this, however, no vocal differences between the sexes or between different age-classes have been documented in any concise studies. Captive adult male Orange Chats are said to give soft notes as a means of prompting females to approach, and parents with food utter similar calls in order to attract their young.

### Food and Feeding

Australian chats feed predominantly on arthropods, some species supplementing the diet with seeds or nectar. They take food items generally from the ground, herbs or low shrubs, but occasionally from tall shrubs or trees.

While some information on food items and feeding behaviour exists for all members of the family, the only one for which the diet and feeding behaviour have been closely studied is the White-fronted Chat. The adults of this species feed mainly on the larvae of small insects, principally beetles (Coleoptera), flies (Diptera), ants and wasps (Hymenoptera) and bugs (Hemiptera). White-fronted Chats also consume the larvae of earwigs (Dermaptera) and lacewings (Neuroptera), but the stomach contents of individuals analysed indicate that these represent only a minor part of the diet. Mites (Acarina), small molluscs, spiders (Araneae) and springtails (Collembola) are known food items of this species, but the evidence suggests that these, likewise, are a minor component of their diet. In addition, this epthianurid takes seeds of acacias (*Acacia*), as well as nectar from various plants, again in small quantity. In one study of White-fronted Chats in southern Victoria, only 0.5% of 226 stomach contents contained seeds.

Other species of Australian chat appear to take similar foods. There is some information on the diet of the Crimson Chat, the known food items of which are similar to those of the White-fronted Chat. The Crimson Chat, however, also consumes larvae of moths and butterflies (Lepidoptera) and nymphs of grasshoppers (Orthoptera), as well as seeds of various chenopods (Chenopodiaceae), including the genera *Rhagodia* and *Sclerolaena*, and grasses (Poaceae). Crimson Chats take nectar from various plant species, including native bean (*Bauhinia*), *Grevillea*, *Hakea* and eucalypts (*Eucalyptus*) or *Corymbia*.

**The Orange Chat,** another family member chiefly confined to Australia's dry interior, often forages on sparsely vegetated flats around saltlakes. It kills prey by beating it against the ground, and manipulates it in its bill before swallowing. In this case the food item is an adult lepidopteran. The Orange Chat is often found singly or in pairs, although it is sometimes reported accompanying mixed-species foraging parties, or feeding in the company of granivorous birds, such as Zebra Finches (*Taeniopygia guttata*).

[*Epthianura aurifrons*,  
Rawlinna,  
Western Australia,  
Australia.

Photo: Graeme Chapman]

Physiological studies have revealed that Australian chats are well adapted to arid environments. Their water requirements are derived largely from food sources, or by metabolism, and they seldom need to drink. Wetlands are also attractive as sources of food. Epthianurids are regularly seen feeding on insects by picking them from the muddy margins of ponds, snatching them from sedges, or making short sallies low over water. Most visits to water for drinking, bathing or foraging take place early or late in the day, hence the long shadow cast by this male Yellow Chat.

[*Epthianura crocea crocea*, SE of Boulia, W Queensland, Australia. Photo: Roland Seitre]

Foods accepted by epthianurids in captivity has been documented for some species, particularly the White-fronted Chat. Captives take a large range of items, including flies, bees, midges, termites (Isoptera) and spiders.

Some species have been seen to drink water. Crimson Chats drink dew on vegetation or take rainwater from small pools in the early morning or late afternoon, but not in the mid-afternoon. There are very few records of epthianurids drinking saline water, but Orange Chats are known to do so on rare occasions. Physiological studies indicate that the members of this family are highly adapted to conditions of high aridity and seldom need to drink. Their water requirements are derived largely from food sources or by metabolism.

Typically, Australian chats capture their food from bare ground, from grassland or from low shrubs or herbs. Occasionally, they take items from atop shrubs or small trees. Crimson Chats sometimes forage among the foliage of trees and shrubs, and on flowers of various species. White-fronted and Yellow Chats will seize food items from muddy substrates or from areas of very shallow water, and the latter species will also glean items from the inflorescences of sedges (Cyperaceae) and grass stems or from floating vegetation in wetlands. Gibberbirds snatch food items from the ground, but they also sally for insects up to 1 m above the ground. Furthermore, both the Gibberbird and the White-fronted Chat take fly larvae from clods of clay, and Gibberbirds have been observed to take maggots from dead sheep. White-fronted Chats are known to feed on freshly tilled soil, following the plough.

Members of this family forage singly, in pairs or in flocks, but Gibberbirds are usually seen to feed as singles or pairs. White-fronted Chats often forage in flocks, sometimes of up to 50 individuals, particularly in autumn and winter. Exceptionally, flocks of over 100 White-fronted Chats have been reported. Mixed-species feeding parties are not uncommon, and flocks containing Crimson, Orange and White-fronted Chats have been observed. In addition, Orange Chats have been recorded as feeding in company with Zebra Finches, and other bird species known to form loose feeding associations with Australian chats include woodswallows (*Artamus*), Australasian Pipits and Common Starlings (*Sturnus vulgaris*). In north-west Western Australia, Yellow Chats have been observed to feed alongside migratory waders, including Oriental Plovers (*Charadrius veredus*), Sharp-tailed Sandpipers (*Calidris acuminata*) and Red Knots (*Calidris canutus*) in wetland habitats.

There is little information available on any age-related, sex-related or geographical variation in the diet or the feeding behaviour of these species. Nestlings and fledglings of the White-fronted Chat are often fed by the parents with insect larvae, particularly caterpillars, but grasshoppers and spiders are also known food items of young.

## Breeding

Few detailed studies of breeding by Australian chats have been undertaken, and most of the information is based on observations of Crimson and White-fronted Chats. The breeding biology of the Yellow Chat and the Gibberbird is poorly documented, and information on the breeding of the Orange Chat is fairly scant. Basic data concerning the breeding season, the nest structure and nest-site, the clutch size and the egg pigmentation are available for all members of the family, but information on reproductive behaviour is lacking for some.

Epthianurids breed mostly as single pairs. There is no evidence for co-operative breeding among the members of this family, but White-fronted Chats often nest in loose groups or semi-colonially, as detailed later in this section.

From the available evidence, it appears that all species are territorial, although almost nothing is known about the territoriality of the Gibberbird. Within a single breeding season simple monogamous pair-bonds appear to be typical, the pair-bond evidently being maintained when a pair attempts to re-nest in the same season. Although the circumstances among Yellow Chats and Gibberbirds are not documented, there is some anecdotal evidence that pairs of these species attend nests. Little is known about the stability of the pair-bond outside the breeding season. For the White-fronted Chat, observations suggest that bonds are not usually maintained over the long term, but some partners are known to reunite in the following breeding season. Evidence derived from observation of captive Crimson and Orange Chats indicates that the pair-bond is not strong.

Rain appears to be the main factor influencing the timing of breeding by Australian chats, particularly in the cases of the nomadic Crimson, Orange and Yellow Chats. Major irruptions of Crimson and Orange Chats are often associated with good rains and concomitant breeding. For some species, such as the White-fronted and Crimson Chats, breeding has been recorded in most

Many insectivorous birds, including Australian chats, provision their nestlings and fledglings with small prey and soft-bodied larvae. This male **White-fronted Chat** is perched alertly on a low bush with a beak full of such items, suggesting that he is returning from a hunting foray to feed his offspring. This species is perhaps the most adaptable eptianurid, occupying a range of habitats—including samphire shrublands, riverbanks, mallee heath, open forest, golf courses and farmland—and using a variety of foraging techniques. It quickly colonizes burnt heaths, and has even been reported following ploughs to forage on freshly tilled soil.

[*Epthianura albifrons*,  
Corunna Station,  
South Australia, Australia.  
Photo: Graeme Chapman]

months, but there are trends in seasonality. In southern and coastal Australia, for example, the White-fronted Chat typically breeds from late winter to late spring, after the winter rains, with some nesting records in summer and autumn if rainfall provides suitable conditions. Farther north, breeding by this species apparently starts earlier. In Western Australia, the Crimson Chat breeds during February to April in the north of its range and progressively later farther south. The breeding season of Yellow Chats is poorly known, but nesting has been recorded through much of the year when conditions are suitable. Most breeding records of the Gibberbird are from September and October, particularly after the first rains, but this species, too, can nest at virtually any time of the year if conditions are conducive. Most members of the family are known to nest more than once in a season. Crimson and Orange Chats may breed two or three times within a year, and White-fronted Chats will nest up to five times in a single year. In one study in Western Australia, a population of White-fronted Chats showed a reduced breeding effort in years with lower winter rainfall.

A distinctive feature of some species is the advertising display-flight performed by the male at the start of the breeding season. That of the Crimson Chat is well described. The male of this species flies from the top of a shrub at one side of his territory in a steep ascent while giving a strong oscillating or clinking call (see Voice); once he reaches the zenith of the flight, the chat holds the wings back and glides in a steep descent while uttering a mournful "tee-wheree" call, and then lands on a shrub at the other side of his territory. These display-flights are sometimes made for the purpose of advertising the territory to opponents, the male exhibiting his red plumage during the flight. At other times these flights take the form of rituals, performed in close proximity to, or directed at, the female. During the display-flights in the proximity of the female, the male raises his crown feathers and spreads his tail feathers. Gibberbirds, too, perform distinctive display-flights in the breeding season, but the flight in this case is said to comprise a vertical stepped climb from the ground, the bird calling during the ascent, followed by a rapid vertical dive back to the ground. Male Yellow Chats make display-flights accompanied by short piping calls, but descriptions of the flight suggest that it is apparently lower and less intense than those of Crimson Chats and Gibberbirds. No display-flights have been documented for the Orange and White-fronted Chats.

Courtship and sexual behaviour are not well documented. Male Crimson Chats are known to raise the red feathers of the

crown when courting, and copulation by this species is initiated by the male, which crouches and tilts his body while shaking his tail in a lateral motion. In the case of the White-fronted Chat, copulation, which is said to last only a few seconds, takes place near the nest three or four days before the first egg is laid.

Agonistic defence of the nesting territory involves both song and movement. Male Crimson Chats exhibit a distinctive territorial posture in which the spread tail is repeatedly dipped and the red crown feathers are raised while the head is simultaneously turned from side to side. Bill-clicking and territorial chases are also given when another Crimson Chat, apart from the male's female partner, approaches the nesting territory. Similarly, male White-fronted and Orange Chats click the bill and make territorial pursuits of rivals, but there is no evidence to suggest that song forms part of the agonistic display. Fighting is rarely reported, although territorial male White-fronted Chats are known to engage in physical contact during territorial chases. A close relationship between territorial behaviour and water loss has been documented for arid-zone species. Mate-guarding is well documented for White-fronted Chats; it can start several weeks before nesting begins, and may relate to a high sex-ratio bias favouring males in certain populations.

Nests are either solitary or placed in loose colonies. Those of White-fronted Chats are sometimes as little as 3–4 m apart, and a density of 18 nests of this species within 0.8 ha has been recorded in southern Victoria. Estimates of the size of the breeding territory vary from 0.2 ha to about 500 m<sup>2</sup> for the Crimson Chat, 15 nests of which have been found within an area of 2.8 ha. Nests are sometimes sited close to nests of other species. For example, Crimson Chat nests have been placed within 20 m of the nest of a pair of White-winged Trillers (*Lalage tricolor*), and within a few metres of a White-fronted Chat's nest.

Epthianurid nests are usually placed in a small shrub, where they are built typically less than 0.5 m above the ground, but occasionally higher. Gibberbirds place the nest on the ground or within a small clump of grass. Samphire species such as *Halosarcia* and *Sarcocornia*, as well as other species of the Chenopodiaceae such as saltbushes, bindyis and bluebushes, are used as nesting sites. Low shrubs around saline lakes and on the edge of watercourses are often selected. Other plants used as nest-sites include grasses, rushes, lignum, and weeds such as thistles (Asteraceae). Live plants are usually used, but dead plants occasionally afford sites for nesting. Nests can be placed near the top

The nest of the **Crimson Chat** is a slightly untidy cup built mostly from plant material, including twigs, grass, bark strips, and rootlets. It is lined and bound with soft material, such as plant down, man-made fibres, animal hair and feathers, including sometimes those of Emus (*Dromaius novaehollandiae*).

The nest is placed within a metre of the ground in a low shrub, most often around 20 cm up. Both sexes are known to share incubation duties, and in this case the male is shown. The incubation period lasts 10–14 days.

[*Epthianura tricolor*, between Bollon and Cunnamulla, SW Queensland, Australia.  
Photo: Raoul Slater/  
Lochman Transparencies]

of a plant or lower down, closer to the ground. Crimson Chats usually conceal their nests at the base of a small shrub, and sometimes on dead fallen branches or among vegetation growing through fallen branches. Nests may be placed in the fork of branches or, less often, among the outer foliage of shrubs. Crimson Chats build the nest at an average of 20 cm above the ground, but the height can vary from ground level to 100 cm up. Epthianurid nests are often detected by the distinctive behaviour of the adults, including the injury-feigning broken-wing display performed nearby. Otherwise, they are usually quite well hidden and can be difficult to locate unless the adults are nearby.

Available evidence indicates that the female builds the nest, although, in the case of some species, both sexes are known to carry nest materials. The task of nest-building has been studied intensively for the White-fronted Chat. With this species, most of the construction work occurs in the early to middle part of the morning, and White-fronted Chats take about ten days to build a nest, but can take as few as six days and as many as 16. Gibberbirds probably require the least amount of time in which to construct a nest, observations indicating that nest-building by this species is completed after six days. Crimson Chats, after the loss of a first clutch, will start to build another nest within five days.

The nests of this family are cup-shaped structures, and they differ subtly among species. Those of the Orange, Yellow and Crimson Chats are rather small cups which are typically neat, but sometimes rather untidy. White-fronted Chats have somewhat bulkier, thicker-walled nests, and Gibberbirds build rather deep cup-shaped nests. The dimensions vary slightly from one species to another. The nests of Orange Chats and Yellow Chats have an external diameter of 9–13 cm and are 3.5–7.5 cm deep externally. Corresponding figures for Crimson Chat nests are 6–14 cm and 4.5–8 cm. The nests of White-fronted Chats have an external diameter of 7–15 cm and an external depth of 6–7 cm. Gibberbird nests measure about 12 cm in diameter, and they are placed in a depression in the ground measuring about 10 cm across and 7–8 cm in depth. Nests are constructed from a range of materials, depending on availability, but typically comprising various combinations of fine twigs, grass stems, hair, including wool, feathers, rootlets, bark fibre, spider egg sacs and plant down. The

feathers of Emus (*Dromaius novaehollandiae*) are sometimes incorporated in nests of Crimson Chats. Other materials utilized by various species include flowers, seeds and such man-made fibres as string. In coastal areas, dried sea-grass (*Posidonia*) is often used by White-fronted and Orange Chats. The materials are woven together, and the structure is lined with finer materials, mainly fine rootlets and grass stems, hair, feathers, spider egg sacs and fine bark pieces.

Australian chats lay oval-shaped eggs which are smooth and sometimes slightly lustrous. Those of most of the species have dimensions of 15–19.5 mm × 11–14 mm, but Gibberbirds' eggs are slightly larger. The ground colour of the eggs of Crimson and White-fronted Chats is usually reddish-white, pinkish-white or white; that of Gibberbird eggs is fleshy white and that of Yellow and Orange Chat eggs is pure white. The markings vary among species. Eggs of White-fronted Chats have reddish-brown, purplish or dark brown blotching or spotting, often concentrated towards the larger end to form a poorly defined penumbral ring or zone. Yellow Chats' eggs have sparse, fine dark brown or blackish-red spotting or dotting, usually confined to the larger end, where the marks sometimes form a penumbral ring. Orange and Crimson Chats have similar egg pigmentation to that of Yellow Chats, but the markings tend to be more prominent and are not confined to the larger end. Inspection of museum collections of clutches indicates that egg pigmentation varies among clutches of the same species, and it is especially difficult to distinguish between the eggs of Orange Chats and those of Crimson Chats.

For species for which adequate information exists, clutch size varies from two to four eggs but typically is of three eggs. Only three-egg clutches have been recorded for the Yellow Chat, but there are few data for this species. White-fronted and Crimson Chats have occasionally been recorded with clutches of five eggs. Laying normally starts within 1–2 days after the nest has been completed, and eggs are laid on consecutive days. Crimson Chats commence laying almost immediately after nest construction is finished. White-fronted Chats are known to start a second clutch as soon as the young of the first brood reach independence. Incidentally, if the first clutch of the latter species fails, a replacement clutch is usually laid in a newly constructed nest.

Incubation is undertaken by both sexes of the Crimson, Orange and White-fronted Chats, but the limited observations on Gibberbirds suggest that only the female of that species incubates. It is said that, in captivity, only the female of the Crimson Chat incubates. For the Yellow Chat, there are no published data on the role of sexes in this respect. The incubation period is 10–14 days for the Crimson Chat, 11–12 for the Orange Chat, and 13–14 days for the White-fronted Chat; no corresponding information is available for the Yellow Chat and the Gibberbird. For those epthianurids for which relevant data exist, incubation starts with the second or third egg laid, but White-fronted Chats may sometimes start to incubate after laying the first egg. The chicks are altricial and nidicolous. They are blind and naked at hatching, but, at least in some species, within a few days they acquire a sparse covering of down. White-fronted Chat nestlings develop feathers by about six days of age, open their eyes when about seven days old and are well feathered by the age of ten days.

Both sexes brood and feed the young and both remove faecal sacs from the nest, but in the case of the White-fronted Chat, at least, only the female broods at night. From the time of incubation until the point at which the young leave the nest, both adults engage in anti-predator distraction displays, which characteristically involve the feigning of injury. Crimson, Orange and White-fronted Chats often perform a distinctive "broken-wing" display while shuffling away from the nest area, and Gibberbirds distract a potential predator's attention by shuffling along the ground, with the wings held lowered, and often rolling the body from side to side.

The nestling period is generally 9–11 days, that of White-fronted Chats tending to be slightly longer, at 10–15 days. After having left the nest, the young are initially unable to fly, but they can run and are therefore able to find shelter or to hide under cover. Fledglings remain in the nesting territory for a few days and are dependent on the adults for up to two weeks. There is little information on the movements of juveniles once they have become independent, but studies of White-fronted Chats suggest that these exhibit little fidelity to the nesting site. White-fronted Chats are able to breed when about one year old, at which time they are still in immature plumage.

Some Australian chats are subject to brood parasitism. Horsfield's Bronze-cuckoo (*Chrysococcyx basalis*) is a widespread

species throughout Australia and is known to lay its eggs in the nests of, among many others, the White-fronted, Crimson and Orange Chats.

There are few data on the breeding success of the Epthianuridae, with the exception of the White-fronted Chat. For this species, hatching success is estimated at 62%, with fledging success estimated at 28–66% depending on the study and the site; an average of 0.71 young is fledged per nest per breeding attempt. In one study of White-fronted Chats in southern Victoria, 30% of nests resulted in at least one young which lived to ten days or more, and 83% of the failures were due to predation. Cats, introduced foxes (*Vulpes*), snakes and other birds, such as the Little Raven (*Corvus mellori*), are known predators of epthianurids. Nest failure results also from desertion and from inclement weather, particularly rain and cold, as well as from the aforementioned brood parasitism. Otherwise, hatching success is about 65% for the Crimson Chat and 64% for the Orange Chat, and the fledging success of Crimson Chats is estimated at 20–26%.

### Movements

Little is known about the movements of Australian chats, and knowledge of this aspect of their lives is complicated, at least in some cases, by seasonal variation in the conspicuousness of the species in question. In Australia, there is also a tendency for human observers to avoid inland areas in summer because of the extreme temperatures, and this has created a strong bias in the seasonal distribution of bird records. Crimson and Orange Chats are largely nomadic, but they also make seasonal movements. Yellow Chats are thought to be similarly nomadic, but there is evidence to suggest that some populations are mainly sedentary. White-fronted Chats apparently vary in their movements, depending on geographical location; they seem to be mostly sedentary, but some evidence suggests that seasonal shifts or nomadism occur. Movements of Gibberbirds are virtually unknown, but nomadism and seasonal movements are again suggested.

The movements of some species are probably related strongly to rainfall events and seasonal conditions. The Crimson Chat is a highly nomadic species, but there may also be a seasonal compo-

The **Orange Chat** has been reported breeding in most months of the year, and sometimes produces three or more broods, depending on local conditions. This species is partially nomadic, arriving and breeding in numbers after good rains. Like other epthianurids, it is socially monogamous, and both sexes contribute to rearing the young. In this instance a male is feeding a brood of two nestlings; the duller female has a pale supercilium, and lacks the black throat. The nestling period usually lasts 10 days.

[*Epthianura aurifrons*,  
Australia.

nent to its movements. Most records of this ephianurid in the northern half of Australia, north of 31° N, are during late summer to winter, and the species is not often recorded in the south of the country during this period. In southern, subcoastal Australia, Crimson Chats are more often recorded in spring and early summer. In parts of coastal south-western and south-eastern Australia, the species is very common in certain years, particularly during inland droughts or periods of low rainfall. In many inland areas of South Australia and Western Australia populations of Crimson Chats are high after good rains, but there is a tendency for numbers to be higher in winter and spring. Large irruptions occur, particularly in arid areas, after good rains, and these invasions are typically accompanied by widespread breeding activity. In arid north-west Western Australia, populations tend to be higher in the wet season, decreasing in the dry season. In the subtropical Kimberley region of Western Australia, immatures are often recorded in the dry season, during autumn and winter, but they are not often recorded in the September–March wet season. Overall, patterns of movement by the Crimson Chat are unpredictable.

As with Crimson Chats, the movements of the Orange Chat are varied and not predictable. Populations of Orange Chats seem often to mirror those of Crimson Chats, and the two are sometimes recorded together in mixed-species flocks, particularly in southern Australia, and at times both are found alongside groups of Australasian Pipits. Major irruptions of Orange Chats occur in arid and semi-arid areas after good rains, but there does appear to

be some seasonality which compounds the complexity of this species' movements. In a few areas, Orange Chats are thought to be largely resident, but their numbers fluctuate. Although the movements of Yellow Chats are very poorly understood, this species' ability to colonize remote areas when permanent water sources are established does suggest the occurrence of nomadic and long-distance movements. Yellow Chats are believed to be resident in parts of north-western Australia, as, for example, around Roebuck Plain, but their numbers fluctuate. In subtropical regions of the Northern Territory, this species is considered to be mainly resident or to undertake localized movements according to seasonal variation in wetland conditions. There may also be short local movements of Yellow Chats in inland Queensland, individuals shifting according to seasonal water availability and vegetation condition around bores and drainages.

The complexity of the movements of Crimson Chats is reflected not only in temporal and geographical variation in populations, but also in the birds' moult patterns. As mentioned earlier (see Morphological Aspects), the primary moult of this species is often arrested or suspended, and many adults show complex moult contrasts within the remiges and rectrices. This suggests that the timing of moult is not so predictable as it is for White-fronted Chats, which undergo a complete post-breeding moult from late spring to autumn, and this fact may reflect a high degree of nomadism and opportunistic breeding. Yellow Chats exhibit a pattern of primary moult similar to that of Crimson Chats.

Few studies of breeding behaviour have focused on the Australian chats, and basic data are lacking for most members of the family. Preliminary fieldwork has shown that the incubation period of the *Crimson Chat* lasts 10–14 days, while the nestling period lasts 9–11 days. Throughout this time both sexes collaborate to raise the young, as illustrated by this image of a male arriving to feed a brood of three nestlings while his partner perches on the rim of the nest. As well as incubating and provisioning, their duties include nest defence: they attempt to distract predators, and to lure them away from the nest, by feigning injury and fluttering along the ground.

[*Ephianura tricolor*, Australia.  
Photo: Michael Morcombe/  
NHPA]

Most clutches of the **Crimson Chat** consist of 2–4 eggs, although up to five eggs have occasionally been reported. According to the results of field studies, around 65% of eggs reach hatching stage, and overall fledging success is 20–26%. These losses are caused by avian brood parasites, such as *Horsfield's Bronze-cuckoo* (*Chrysococcyx basalis*) and predatory birds, such as the *Little Raven* (*Corvus mellori*), as well as introduced foxes (*Vulpes*) and cats. Here, a male feeds a brood of four nestlings with larval lepidopterans.

Photo: Stanley Breeden/  
Lochman Transparencies]

Insufficient ringing data exist for any accurate determination of the movements made by the members of this family. Almost all recaptures are from places less than 10 km from the original site of ringing, but there is a record of a ringed White-fronted Chat being recovered more than 10 km from the initial site. Crimson and White-fronted Chats sometimes arrive in areas just a few months after a fire has taken place, including sites where they had not previously been recorded, but this may be a result of local nomadism rather than broad-scale movements.

### Relationship with Man

Indigenous people in Australia had names for certain species of bird and other animals. The name "Nyee-nyee" was applied by some tribes to both the Crimson Chat and the White-fronted Chat, probably referring to the calls of these epthianurids. Similarly, the Orange and White-fronted Chats are sometimes given the colloquial name of "Tang", which is the sound of the flight call made by these species.

Otherwise, there is little information on the influence of these birds on human thinking or behaviour. The fact that they inhabit arid areas where human beings, if present at all, are very sparsely scattered presumably has something to do with this.

### Status and Conservation

No member of the Epthianuridae is globally threatened. Indeed, of the five species, only the Yellow Chat is considered to have significant conservation issues. Its subspecies *macgregori*, from central-eastern Queensland, is considered "critically endangered" under both national and state legislation. This form was probably never common, and it was thought even to have become extinct in the early part of the twentieth century, but there have been recent discoveries of *macgregori* in the Fitzroy River Basin and on Curtis Island, in eastern Queensland. The subspecies *tunneyi* of the Yellow Chat, which is restricted to the north-west part of Northern Territory, is regarded as "endangered". Excessive grazing by stock, and weed infestation, may adversely affect populations of this species, which is considered of special concern at a national level.

On the positive side, White-fronted Chats have probably benefited from the widespread clearance of native vegetation for agriculture and pastoral activity, as evidenced by their preference for open pastures and farmland. The development of land for housing and industrial facilities, however, has led to declines in the numbers of this species in parts of southern Australia, particularly in the larger urban areas, and especially on the coasts of south-eastern Queensland and northern New South Wales.

In contrast, there is little or no evidence to suggest that the Crimson Chat, the Orange Chat and the Gibberbird are threatened in any way. Indeed, it has been suggested that Gibberbirds may have benefited from modification of arid-zone vegetation through pastoral activity, although the evidence for this is fairly scant.

Continuing pressure of urban development, weed infestation, introduced predators and overgrazing are likely to have detrimental effects on certain species, particularly those in coastal and subcoastal areas. Cats and other introduced predators are known to take some epthianurid species, and some of these birds are killed by vehicles. Vehicles and the trampling of vegetation by grazing stock also destroy nests, but it is not known to what extent this has affected populations. The establishment of permanent water sources such as bores and overflows in arid regions may have benefited some species, particularly the Yellow Chat, but the extent to which this is counteracted by degradation of vegetation by livestock remains unknown.

PLATE 49

## PLATE 49

## Family EPTHIANURIDAE (AUSTRALIAN CHATS) SPECIES ACCOUNTS

### Genus *EPTHIANURA* Gould, 1838

#### 1. Crimson Chat

##### *Epthianura tricolor*

**French:** Epthianure tricolore **German:** Scharlachtrugschmätzer **Spanish:** Eptianuro Tricolor  
**Other common names:** Red-breasted Chat, Crimson-breasted Nun, Saltbush Canary

**Taxonomy.** *Epthianura tricolor* Gould, 1841, Australia, 'Hab.?' = Peel River, New South Wales, Australia.

Genus name often spelt erroneously as *Ephthianura*. Genus was in the past sometimes placed in thornbill family (Acanthizidae), and more recent analyses of DNA-DNA hybridization indicate that it belongs with the honeyeaters (Meliphagidae); further study required. Monotypic.

**Distribution.** Australia, mainly in interior, with few records from N tropics.

**Descriptive notes.** 11–13 cm; 9–14 g. Distinctive Australian chat with scarlet or reddish uppertail-coverts in all plumages. Male in breeding plumage has forehead, crown and nape scarlet; lores and broad band back to neck side dark brown, this colour extending down to side of upper breast;

upperparts brown, except for scarlet uppertail-coverts; upperwing mostly dark brown, with narrow white outer edges and broad tips on median and greater secondary coverts, narrow white fringes on alula, greater primary coverts, tertials and secondaries, and narrow white fringes at tips of primaries; tail blackish-brown, feathers with narrow white outer edges and tips (more obvious in flight); chin and throat white; underparts mostly scarlet, lower belly, thighs and undertail-coverts white, sometimes with scarlet mottling; underwing-coverts and axillaries pale brownish-grey; iris pale yellow to whitish; bill and legs black to dark grey. Male in non-breeding plumage (mainly Apr–Jun) is less extensively scarlet on top of head and underparts, and has paler brown facial mask, neck and side of upper breast. Female differs from male in having top and side of head, neck and side of upper breast light brownish, sometimes with faint orange or pinkish tinge on forehead and crown, and whitish underparts with pinkish mottling on lower breast, belly and flanks. Juvenile is similar to female, but has dull orange uppertail-coverts, lacks red or pink colour below, and has broad buff fringes on all upperwing feathers; immature very similar to adult. **VOICE.** Mournful "tee-who" or strong oscillating calls given by territorial

male, also bill-clicking in agonistic display. Chattering, metallic or nasal notes given by flocks and in flight; sweet "see" whistle as alarm or contact call.

**Habitat.** Open chenopod shrublands, or shrublands dominated by acacia (*Acacia*, especially *mulgas*), *Grevillea*, *Hakea* and *Eremophila*, in arid or semi-arid regions, and occasionally in temperate or subtropical regions; occurs also in grasslands, particularly those dominated by spinifex (*Triodia*) or Mitchell grass (*Asprella*), and sometimes in woodland. Often on plains, along watercourses, on dunes or edges of saltlakes, and occasionally on agricultural land.

**Food and Feeding.** Eats insects, including beetles (Coleoptera), grasshoppers (Orthoptera), bugs (Hemiptera), butterflies (Lepidoptera) and ants (Hymenoptera); also arachnids, nectar, fruits and seeds. Drinks water, including dew. Often forages on ground or probes among foliage or flowers of low shrubs. Usually in small groups or flocks of up to 30 individuals, sometimes in mixed-species flocks with other chats.

**Breeding.** Usually Jul/Aug–Nov/Dec, sometimes in other months after good rainfall in arid regions. Breeds in pairs; both sexes take part in nest-building, defence of nest territory, incubation and rearing of young. Nest a neat, small cup made from grass, fine stems, bark fibre, feathers and rootlets, often bound with hair, feathers, often those of Emu (*Dromaius novaehollandiae*), soft seeds and plant down; placed 0–120 cm (usually not above 40 cm) above ground, usually in low shrub, typically saltbush (*Atriplex*), bluebush (*Maireana*) or samphire (*Halosarcia*, *Sarcocornia*), but sometimes in cluster of spinifex, tall grasses, small tree, among dead branches on ground or in introduced tall weeds such as thistles or horchound (*Marrubium vulgare*). Clutch 2–4 eggs, rarely 5; incubation period 10–14 days; nestling period 9–11 days. Rarely, nests parasitized by Horsfield's Bronze-cuckoo (*Chrysococcyx basalis*). Hatching success c. 65% and fledging success 20–26%; introduced foxes (*Vulpes*) sometimes destroy nests, and cats may kill nestlings.

**Movements.** Highly nomadic, local numbers fluctuating enormously. Seasonal trends poorly understood and unpredictable; in breeding range in SE & SW, usually recorded in spring–summer and particularly in years of high rainfall; in N parts of range, such as Kimberley region of Western Australia and in N Queensland (excluding Cape York Peninsula), usually recorded as non-breeding visitor in autumn–winter (dry season). In C parts, including N South Australia and arid Western Australia, most numerous after good rainfall; drought conditions in C Australia apparently lead to large-scale movements to coastal or S regions.

**Status and Conservation.** Not globally threatened. Locally common. Densities of up to 3–7 birds/ha recorded at L Disappointment, in Western Australia. Successfully bred in captivity.

**Bibliography.** Barrett *et al.* (2003), Blakers *et al.* (1984), Chandler (1929), Clayton *et al.* (2006), Davies *et al.* (1988), Davis (1999), Harrison (1974b), Higgins *et al.* (2001), Hobbs (1961), Johnstone & Keast (1958c), Kolichis (1992), McAllan & Bruce (1989), Milhinch (1983), Schodde & Mason (1999), Shephard (1989), White (1950a), Williams (1979).

## 2. Orange Chat

### *Ephthianura aurifrons*

**French:** Ephthianure orangée **German:** Goldstirn-Trugschmätzer **Spanish:** Eptianuro Naranja  
**Other common names:** Orange-breasted/Orange-fronted Chat, Orange-fronted Nun, Tang, Saltbush Canary

**Taxonomy.** *Ephthianura aurifrons* Gould, 1838, Gammon Plains, New South Wales, Australia. Genus name often spelt erroneously as *Ephthianura*. Genus was in the past sometimes placed in thornbill family (Acanthizidae), and more recent analyses of DNA–DNA hybridization indicate that it belongs with the honeyeaters (Meliphagidae); further study required. Monotypic.

**Distribution.** Australia, mainly in interior, with few records from N tropics.

**Descriptive notes.** 11–12 cm; 8–13 g. Distinctive Australian chat with yellow upperpart-coverts in all plumages. Male has forehead rich orange, grading to yellow on crown, eyering, ear-coverts and side of neck; nape, hindneck and most of upperparts yellow-olive, dark brown mottling or streaking on nape, mantle, back and scapulars; bright yellow upperpart-coverts; upwings dark brown to blackish-brown, with yellow-white or whitish fringes on alula and all wing-coverts, tertials with yellow-white fringes, primaries and secondaries with narrow yellow outer edges, and primaries with narrow white fringes at tips (when fresh); rectrices blackish-brown, paler on undersurface, with narrow white tips; lores, chin and throat black, forming distinct black mask; underparts orange-yellow or rich yellow, with fine dark brown streaks on upper flanks; underwing greyish, axillaries yellow; iris reddish-brown or orange; bill and legs black to greyish-brown. Female lacks black facial mask and rich orange plumage, has top of head, neck and upperparts greyish-brown with fine dusky streaking, ear-coverts light brownish with yellow tinge, lores and chin whitish, grading to pale yellow on throat, eyering and supercilium; upwings as male, but median secondary coverts and tertials fringed light brownish and greater secondary coverts fringed brownish-white; underparts paler yellow, with light brown wash at breast side and fine brown streaking on breast and upper flanks; bill usually paler brown at base. Juvenile is similar to female, but fringes of tertials and upwings-coverts broader and richer buff-brown, and underbody much paler yellow or whitish, with buff wash across breast, bill brownish with dusky tip, gape yellow, legs brownish-orange; immature very similar to adult female. Voice. Not well known. Weak metallic song or rising metallic rasp given from top of shrub. Metallic "tang" or mellow "cheek cheek" in flight; soft "shu-shu-shu" during broken-wing display.

**Habitat.** Open chenopod shrublands and stony areas of arid or semi-arid regions, occasionally in coastal or near-coastal regions. Often in samphire vegetation around edges of saltlakes; sometimes in low mulga (*Acacia*) woodland or tall shrubland dominated by *Eremophila*, *Grevillea* and other species. Occasionally recorded in spinifex (*Triodia*) or other grassland, but rarely on agricultural land.

**Food and Feeding.** Eats insects, including small grasshoppers (Orthoptera), beetles (Coleoptera), caterpillars (Lepidoptera) and flies (Diptera); also small spiders (Araneae), and vegetable matter. Apparently no records of feeding on nectar. Rarely drinks water. Forages on ground or in low shrubs. In pairs or small groups, at times in larger flocks; sometimes in mixed-species parties, including those with other chats.

**Breeding.** Breeds in most months except May–Jun, but usually Aug–Nov; sometimes three or more nestings in a year. Breeds in pairs; both sexes take part in nest-building, and both defend nest

territory, incubate eggs and rear young. Nest, built mostly by female, a small cup constructed from fine twigs, rootlets, grass, feathers and, in coastal areas, sea-grass (*Posidonia*), bound with hair, wool, spider egg sacs, feathers and fine grasses and rootlets; placed 10–30 cm above ground, sometimes on ground, and usually in low shrub, typically saltbush (*Atriplex*), bluebush (*Maireana*) or samphire (*Halosarcia*, *Sarcocornia*), sometimes in cluster of spinifex, canegrass (*Eragrostis*) or lignum (*Muehlenbeckia*). Clutch usually 3 eggs, sometimes 2 or 4; incubation period 11–12 days; nestling period c. 10 days. Nests sometimes parasitized by Horsfield's Bronze-cuckoo (*Chrysococcyx basalis*). Hatching success c. 64%, but no information on fledging success.

**Movements.** Nomadic, but some seasonal trends noted; in a few regions present throughout year, though numbers vary. Major irruptions sometimes occur at edges of range during drought conditions. In arid and semi-arid regions, abundance usually greatest after good rains; abundance highest in interior Western Australia after good summer or autumn rains, and not often recorded during spring to early summer; in Victoria and S South Australia usually recorded only in spring–summer, seldom in winter.

**Status and Conservation.** Not globally threatened. Locally fairly common. Densities of 0.72 birds/ha at Cunumulla (Queensland) and exceeding 0.06 birds/ha near Broken Hill (New South Wales). Said to have been resident in Riverina region of New South Wales, but now irregular visitor there following dieback of saltbush. Has bred successfully in captivity.

**Bibliography.** Anon. (1981), Barrett *et al.* (2003), Beruldsen (1980), Blakers *et al.* (1984), Clayton *et al.* (2006), Cleland (1922), Cody (1991), Harrison (1974b), Higgins *et al.* (2001), Hindwood (1940a), Hobbs (1961), Johnstone & Keast (1958c), Keast (1958c), McAllan (1989), McAllan & Bruce (1989), McGilp (1923), Richards (1982), Schodde & Mason (1999), Shephard (1989), Smith (1997), Stephens (1983), Williams (1979), Williams & Main (1976).

## 3. Yellow Chat

### *Ephthianura crocea*

**French:** Ephthianure à collier **German:** Safrantrugschmätzer **Spanish:** Eptianuro Amarillo  
**Other common names:** Yellow-breasted Chat

**Taxonomy.** *Ephthianura crocea* Castelnau and E. P. Ramsay, 1877, Norman River, Queensland, Australia.

Genus name often spelt erroneously as *Ephthianura*. Genus was in the past sometimes placed in thornbill family (Acanthizidae), and more recent analyses of DNA–DNA hybridization indicate that it belongs with the honeyeaters (Meliphagidae); further study required. Proposed race *boweri* (King Sound and R Fitzroy, in N Western Australia) now considered synonymous with nominate. Three subspecies recognized.

**Subspecies and Distribution.**

*E. c. tunneyi* Mathews, 1912 – NW Northern Territory (W Arnhem Land).

*E. c. crocea* Castelnau & E. P. Ramsay, 1877 – N Western Australia (SW & NE Kimberley region, King Sound and R Fitzroy) E patchily to E Northern Territory (Barkley Tableland) and W Queensland, thence S to NE South Australia (Fromanga–L Eyre Basin).

*E. c. macgregori* Keast, 1958 – lower Dawson–Mackenzie Basin, in CE Queensland.

**Descriptive notes.** 11–12 cm; 7–10 g. Distinctive yellowish chat. Male nominate race in breeding plumage is unmistakable: has most of head and neck orange-yellow or bright yellow with narrow black lateral stripe; yellow-olive nape, hindneck and mantle to rump, with fine brown streaks on mantle, back and scapulars; uppertail-coverts orange-yellow; upwings dark brown, wing-coverts with narrow yellow or yellow-white fringes (forming pair of obvious wingbars on median and greater coverts), tertials with broad white fringes, primaries and secondaries with narrow yellow outer edges and narrow white fringes at tips;

rectrices black-brown, central pair with narrow yellow fringes, remaining pairs with narrow white tips and yellow outer edges; underbody orange-yellow or bright yellow, distinctive black crescent across centre of upper breast; underwing-coverts and axillaries yellow-white; iris whitish, cream or light brownish-grey; bill, gape and legs black to grey-black or brownish. Male non-breeding is similar to breeding-plumaged male, but differs in having olive-grey ground colour on top of head, neck and upperparts (to rump), yellowish-white face, ear-coverts and narrow supercilium, no black lateral stripe; below, paler yellow or whitish with scattered yellow patches, with diffuse blackish or dark brown crescent or small smudge on upper breast; bill paler grey or pinkish-brown at base. Female is similar to non-breeding male, but lacks dark breast mark; differs from very similar female *E. aurifrons* mainly in pale iris, whitish (not brownish) fringes of median and greater upwings-coverts, olive-grey (rather than greyish-brown) head top, ear-coverts and most of upperparts. Juvenile is very similar to female, but iris greyish and gape yellow; immature probably difficult to separate from adult. Race *tunneyi* in breeding plumage is similar to nominate, but yellow or yellow-orange colour richer, and male has slightly broader black crescent across breast; *macgregori* is apparently similar to nominate, but breeding male has darker yellowish-olive upperparts with streaks obscure, richer yellow-orange underparts, broader black breast-crescent. Voice. Song, often given by male when perched, a high-pitched "tee-tsu-tee" or "pee-ee", individual notes varying in pitch; metallic "tee-tee-tee" by male in display-flight. Occasional other calls include nasal "nang", and churring notes during broken-wing display.

**Habitat.** Low vegetation surrounding ephemeral wetlands, including samphire and freshwater swamps, bore overflows, saltlakes, sewage ponds and floodplains, in arid, semi-arid and tropical regions; sometimes in open acacia (*Acacia*) or eucalypt (*Eucalyptus*) woodlands with lignum (*Muehlenbeckia*), grassy or chenopod understorey. In NW Australia, has been recorded in tall *Sporobolus* grasslands associated with semi-permanent subcoastal wetlands; in N tropics, occasionally occurs at edges of mangrove stands.

**Food and Feeding.** Food mainly insects, including ants (of family Formicidae), beetles (of family Chrysomelidae), moths and caterpillars (Lepidoptera) and flies (Diptera); also arachnids. Often forages on wet ground, and also in small shrubs and grasses. Forages singly or in small flocks; sometimes in mixed-species parties, including those with *E. aurifrons*.

**Breeding.** Recorded in all months except Feb, Aug and Sept. Little information on bonds and breeding behaviour. Nest a small cup made of grasses or fine stems, and sometimes spider egg sacs or feathers, lined with fine rootlets, feathers, hair and spider egg sacs; placed up to 1.2 m above

ground in clump of grass or sedge, low shrub or lignum, sometimes in flooded area. Clutch 3 eggs; no information on incubation period; young fed by both sexes, nestling period 11–12 days.

**Movements.** Not understood. Probably largely nomadic, and locally and/or seasonally common at some localities in Kimberley region of Western Australia; thought to be resident at some locations, e.g. Roeback Plains (Western Australia) and Coorabulka Station (SW Queensland). Leaves wetlands and bore overflows as they dry out.

**Status and Conservation.** Not globally threatened. Locally fairly common to rare; rarer and more locally distributed than other members of family. Some concern for certain populations. Nominate race considered "vulnerable" in Queensland and "rare" in South Australia, and there are unconfirmed records of this race from inland New South Wales; sinking of artesian bores may have resulted in expansion of range to SW Queensland since 1890s; historical records from Gulf of Carpentaria region, but not recorded there since 1930s. E Queensland race *macgregori* "critically endangered"; thought to be extinct after c. 1917, but recorded on Curtis I in 1993, and more recently from several mainland sites in Fitzroy River Basin and Broad Sound, N of Rockhampton; no published breeding records of this race, and fieldwork is required. Race *tunneyi* is considered "endangered" in Northern Territory. Excessive grazing by livestock, as well as weed infestation, may adversely affect populations of this species.

**Bibliography.** Barrett *et al.* (2003), Black *et al.* (1983), Blakers *et al.* (1984), Eckert & Ludewigs (2003), Ford & Parker (1972, 1974), Higgins *et al.* (2001), Horton (1975, 1982), Juensch & Vervest (1990), Johnstone & Storr (2005), Keast (1958c), McAllan & Bruce (1989), Reynolds *et al.* (1982), Schodde & Mason (1999), Strong & Fleming (1987), Williams (1979), Woodall (1982).

#### 4. White-fronted Chat

##### *Epthianura albifrons*

**French:** Epthianure à front blanc **German:** Weißgesicht-Trugschmätzer **Spanish:** Eptianuro Pio  
**Other common names:** White-faced Chat, White-fronted Bushchat, Tang

**Taxonomy.** *Acanthiza albiglans* Jardine and Selby, 1828, New Holland = New South Wales, Australia.

Genus name often spelt erroneously as *Ephthianura*. Genus was in the past sometimes placed in thornbill family (Acanthizidae), and more recent analyses of DNA-DNA hybridization indicate that it belongs with the honeyeaters (Meliphagidae); further study required. Tasmanian birds exhibit tendency towards larger size (mainly bill) than those from mainland Australia; described as a race, *tasmanica*, but differences slight and recognition of geographical races considered unwarranted. Monotypic.

**Distribution.** S Western Australia (S from c. 23° S in far W) E to South Australia (mainly S of 30° S), New South Wales, Victoria and Tasmania.

**Descriptive notes.** 11–13 cm; 11–17 g. Distinctive Australian chat with rather robust body. Male has most of head and upper breast white; rear crown, nape and hindneck black, this colour continuing as broad black band down side of neck and across lower breast; most of upperparts light grey with faint dark brown streaking, uppertail-coverts black; upperwing blackish (becoming brown with wear), tertials with fine whitish fringes when fresh; rectrices blackish, all except innermost pair with broad white tips on inner webs; belly to undertail-coverts white, thighs blackish; underwing-coverts and axillaries blackish-brown or dark

brown; iris orange or reddish to buff or light greyish; bill, gape and legs black or grey. Female differs from male in having top and sides of head and neck light greyish, short white supercilium, narrow white eyering; most of upperparts light brownish-grey with fine brown mottling, uppertail-coverts dark brownish, upperwing dark brown, light brown fringes on median and greater coverts, alula, tertials, secondaries and inner primaries, narrow whitish outer edge and fringe around tip on outer primaries; rectrices black-brown, white tips slightly narrower than on male; chin and throat white, most of underbody whitish, but breast side and flanks brownish-grey or buff, and broad blackish-brown crescent across centre of breast; axillaries and underwing-coverts brownish-grey. Juvenile is similar to female, but head top to neck and upperparts grey-brown or light brownish, underbody whitish with diffuse, narrow brownish breastband, upperwing-coverts and tertials with broad light brown fringes, primaries and secondaries with narrow light brown outer edges, iris pinkish-brown to buff, cream or light grey, gape yellow; immature similar to adults of corresponding sex, upperwing of young male often showing contrast between black (replaced in moult) and dark brown (retained juvenile) feathers. Voice. Distinctive nasal "tang", rather like call of Zebra Finch (*Taeniopygia guttata*), often given in flight; sometimes a plaintive piping call or sharp "whit whit" in display-flight.

**Habitat.** Mainly open treeless habitats, such as grasslands, low shrublands and low vegetation usually less than 1 m tall surrounding wetlands, in temperate and semi-arid regions. Often in samphire or chenopod shrublands, rank vegetation surrounding freshwater wetlands, coastal dune vegetation, sandy beaches, roadside vegetation, farmland, and recreation sites such as golf courses; occasionally in heath, woodland or open forest in early stages of regeneration after fire or clearance.

**Food and Feeding.** Eats mostly insects, including beetles (Coleoptera), bugs (Hemiptera), flies (Diptera), ants and bees (Hymenoptera), caterpillars and adult moths (Lepidoptera) and grasshoppers (Orthoptera); also spiders (Araneae), and occasionally small gastropods (Mollusca), springtails (Collembola, of family Isotomidae) and isopods (Crustacea); sometimes seeds, nectar or fruit, including seeds of acacias (*Acacia*). Occasionally drinks water. Usually takes food from ground or in low shrubs, sometimes also from shallow water; sometimes by sallying for aerial insects. Forages singly or in small groups, occasionally in flocks of more than 50 individuals; sometimes in mixed-species flocks.

**Breeding.** Jun–Jan, sometimes in other months; in arid regions usually dependent on good winter rainfall, but can breed in late summer and autumn if conditions suitable. Breeds in simple pairs.

Nest built by female, a deep cup made from grass, fine stems, leaves, rootlets, and sometimes other materials such as wool or sea-grass (*Posidonia*), usually lined with fine grass, rootlets, feathers, wool and hair, generally less than 1 m above ground in low shrub, clump of grass or sedge, sometimes on ground. Clutch 2–4 eggs, usually 3, rarely 5; incubation by both sexes, period 13–14 days; chicks fed by both sexes, nestling period 10–15 days. Nests occasionally parasitized by Horsfield's Bronze-cuckoo (*Chrysococcyx basalis*) and rarely by Fan-tailed Cuckoo (*Cacomantis flabelliformis*). Hatching success c. 60% and fledging success c. 25%.

**Movements.** Not fully understood. In many areas, species occurs throughout year and considered resident or sedentary; seasonal visitor to many other areas, including Swan Plain, in Western Australia, where fairly regular in summer–autumn; in other areas considered nomadic or irregular visitor, e.g. occasional records from SW Queensland. Possibly moves inland during good winter rains.

**Status and Conservation.** Not globally threatened. Fairly common. May have benefited from clearance of woodland for agriculture; urban and industrial development in Sydney region of New South Wales has led to declines there.

**Bibliography.** Barrett *et al.* (2003), Blakers *et al.* (1984), Higgins *et al.* (2001), Hobbs (1961), Johnstone & Storr (2005), Keast (1958c), Kolichis (1992), Major (1991a, 1991b, 1992), Masters & Milhinch (1974), McAllan & Bruce (1989), Schodde & Mason (1999), Watson (1955), Wheeler (1950), Williams (1979), Williams & Main (1976).

#### Genus *ASHBYIA* North, 1911

##### 5. Gibberbird

##### *Ashbyia lovensis*

**French:** Epthianure d'Ashby **German:** Wüstentrugschmätzer **Spanish:** Eptianuro de Ashby  
**Other common names:** Desert/Gibber Chat, Desert Bird

**Taxonomy.** *Ephthianura lovensis* Ashby, 1911, Leigh Creek, South Australia.

Genus was in the past sometimes placed in thornbill family (Acanthizidae), and more recent analyses of DNA-DNA hybridization indicate that it belongs with the honeyeaters (Meliphagidae); further study required. Monotypic.

**Distribution.** Extreme S Northern Territory and SW Queensland S to N South Australia and NW New South Wales.

**Descriptive notes.** 11–14 cm; 14–20 g. Distinctive Australian chat with robust body, short primary projection and rather heavy bill. Male has top of head, ear-coverts and neck light brownish-grey, forehead and ear-coverts washed yellow, yellow lores and supercilium; upperparts pinkish-brown with diffuse dark brown streaking; upperwing dark brown, tertials and all secondary wing-coverts with broad pink-brown fringes (forming pair of wingbars on median and greater coverts), primaries and secondaries with buff outer edges and narrow white fringes at tips; rectrices dark brown with narrow buff or whitish tips, outermost feather pair with distinct white outer edges; chin, throat and underparts yellow, faint pinkish-brown wash on breast side and flanks; underwing-coverts and axillaries yellowish-white; iris pale yellow to cream or white; bill and gape blackish or dark grey; legs dark grey or brownish, often with pinkish tinge. Female is similar to male, but yellow areas paler, top of head and upperparts pinkish-brown, and pinkish-brown wash often extends across breast. Juvenile is similar to female, but with buff lores and faint supercilium, whitish chin and throat, and pale yellow or flesh-coloured gape; immature not separable from adult in the field. Voice. Clear sweet ascending or descending piping song. One or more sharp "whit" notes given in alarm or display.

**Habitat.** Sparsely vegetated stony or gibber deserts in arid regions, including very open shrubland-grassland with saltbush (*Atriplex*), bindyi (*Sclerolaena*) and Mitchell grass (*Astrelba*); occasionally on claypans with open saltbush vegetation.

**Food and Feeding.** Eats mostly insects, including beetles (Coleoptera), bugs (Hemiptera), ants (of family Formicidae) and caterpillars (Lepidoptera); also seeds, including those of grasses, and vegetable matter. Forages on ground, singly or in twos, occasionally in small groups.

**Breeding.** Poorly understood. Breeding recorded in all months, usually Sept–Oct, possibly nesting after good rains. Apparently breeds in simple pairs, and both sexes take part in nest-building, incubation and the rearing of young. Nest a deep cup made from fine stems, grass, rootlets and sometimes feathers or hair, lined with rootlets, fine grass and other plant materials such as flowerheads of daisies (Compositae), placed in shallow depression in ground. Clutch 2–4 eggs, usually 3 in good seasons; no information on duration of incubation and fledging periods. Hatching success 50% for four eggs in two nests.

**Movements.** Not understood. Possibly partly nomadic; in some areas, fairly common after good rains and scarce during drought. Possibly capable of long-distance movements, as vagrants in SC Western Australia were more than 1000 km from nearest area where regularly recorded (in South Australia).

**Status and Conservation.** Not globally threatened. Uncommon. Has possibly benefited from introduction of stock in NE South Australia, through modification of habitat and increased insect larvae in winter.

**Bibliography.** Barrett *et al.* (2003), Blakers *et al.* (1984), Boehm (1957), Higgins *et al.* (2001), Keast (1958c), Kloot (1998), Love (1917), McAllan & Bruce (1989), McGilp (1919, 1921), Parker (1980a), Rose (1999), Schodde & Mason (1999), Schrader (1976), Smith (1973), White (1917), Wilson (1974), Woodhouse (1974).

## Class AVES

## Order PASSERIFORMES

## Suborder OSCINES

## Family NEOSITTIDAE (SITTELLAS)

- Small, dumpy passerines with short tail, disproportionately long and broad wings, dagger-shaped or slightly upturned bill, and rather short legs with long toes; one species mostly black, the other brown and white with variable streaking.
- 10–14 cm.

- Australia and New Guinea.
- Forest and woodland, one species in montane rainforest.
- 1 genus, 2 species, 14 taxa.
- No species threatened; none extinct since 1600.

## Systematics

Like the Australasian treecreepers (Climacteridae), the sittellas (Neosittidae) provide a striking illustration of parallel evolution between an ancient Australasian endemic oscine family and another, distantly related, largely Northern Hemisphere family. Indeed, the close resemblance of sittellas to the nuthatches (Sittidae) in both morphology and climbing locomotion was so impressive that the sittellas were considered to belong in the nuthatch family until as recently as 1967. Over a decade earlier E. Mayr had questioned their placement in Sittidae, because of differences in their nests and sociality. Sittellas build a beautifully camouflaged, deep cup-shaped nest in a vertical forked branch and are highly social, co-operatively breeding birds, whereas nuthatches nest in tree holes and most species breed as simple pairs. Anatomical studies in 1977 showed that, despite the very close similarity between the sittellas and the nuthatches in climbing techniques, sittellas are much more similar in leg musculature to the Australasian honeyeaters (Meliphagidae) than to the nuthatches.

Although checklists drawn up in the 1950s and 1960s placed the sittellas variously among the babblers (Timaliidae), the Holarctic and Afrotropical treecreepers (Certhiidae) and the Australasian treecreepers, the true affinities of this tiny family remained unclear. On the basis of similarities in egg coloration, juvenile plumage and nest structure, S. A. Parker proposed that sittellas could have arisen from the ancestors of the Australasian robins (Petroicidae), the whistlers (Pachycephalidae) or the monarch-flycatchers (Monarchidae). Soon afterwards, the studies undertaken by C. G. Sibley and J. E. Ahlquist on DNA–DNA hybridization seemed to vindicate Parker's proposal, indicating that the closest living relatives of the sittellas were the whistlers and the monarchs. Consequently, these authors placed sittellas in a monogeneric tribe, Neosittini, within a subfamily Pachycephalinae of the outsize family Corvidae. The most recent phylogenetic analysis of oscine passerines, based on mainly molecular data-sets, places the sittellas in a clade of their own, closest to the berrypeckers and longbills (Melanocharitidae) of New Guinea, and closer to the whistlers than the monarchs. While the affinities of sittellas are thus still uncertain, there now seems little doubt that their morphological and locomotory similarities to the nuthatches are due entirely to evolutionary convergence resulting from adaptations for bark-foraging.

The historical "identity crisis" suffered by the family as a whole also characterizes the species within it. The Varied Sittella

(*Daphoenositta chrysoptera*) was first described from Sydney, south-east Australia, in 1801, under the name of the "Orange-winged Nuthatch (*Sitta chrysoptera*)". When it became clear that it did not belong within *Sitta*, a separate genus was required, and *Sittella* was thus erected by W. Swainson in 1837. However, this name turned out to be preoccupied by an 1815 synonym for *Sitta*, as a result of which the Australasian genus was renamed *Neositta* by C. E. Hellmayr in 1901. In the meantime, in 1896, the Black Sittella (*Daphoenositta miranda*) had been discovered in south-east New Guinea, and placed in a separate new genus, *Daphoenositta*. Moving forward once again, to 1904, R. Ridgway coined the first family-group name for these birds, when he included both *Neositta* and *Daphoenositta* in his subfamily Neosittinae. Subsequently, from the 1960s onwards the two genera were increasingly considered more suitably lumped into a single genus, in which case the older name, *Daphoenositta*, has priority. Thus, the sittellas end up with the unusual situation whereby the oldest valid name for the family, Neosittidae, is based on a genus currently subsumed into the older genus name *Daphoenositta*. A. L. Rand already attempted to oust the name Neosittinae way back in 1936, proposing Daphoenosittinae as a replacement, on the grounds simply that *Daphoenositta* was the older genus name, but there is no nomenclatural justification for such a change. Indeed, despite the evident awkwardness of the current situation, the International Code of Zoological Nomenclature is quite clear on the issue, to the extent that the particular case of Neosittidae is the very one cited within the text of the Code to exemplify the principle that the valid family-group name need not be based on the oldest available genus name.

The five distinctive, allopatric Australian subspecies of the Varied Sittella were generally considered to represent five separate species until 1950, when Mayr claimed that almost all forms interbred where their ranges abutted on one another, and that they should, therefore, be treated as members of one and the same species. Since then, hybridization has been confirmed between all contiguous forms, culminating in the discovery of five-way hybridization in central Queensland, where all subspecies meet, involving the segregation and recombination of at least ten different morphological characteristics.

The Papuan forms of the Varied Sittella are similarly variable. Although they are sometimes treated as a separate full species, the "Papuan Sittella (*Daphoenositta papuensis*)", because of their lack of a distinct wingbar and their confinement to montane forests, they are fairly similar in body plumage, bill col-

The two species of *sittella* are small, dumpy, short-tailed passerines with a dagger-shaped or slightly upturned bill. They have broad wings, short legs, and small feet, but the toes are rather long—an adaptation to a life spent clinging onto trees. Unlike the case of most climbing birds, the hind toe of the **Varied Sittella** is curved.

When climbing, *sittellas* hold the body at an oblique angle to the trunk, keeping their feet parallel and widely spread, and ascend in a series of hops, lifting both feet simultaneously.

[*Daphoenositta chrysoptera pileata*, Dadswells Bridge, W Victoria, Australia. Photo: Jon Thornton]

our, and in habitat elevation to the north-east Australian subspecies *striata*, to which they were probably linked during one of the most recent ice ages. Thus, the Papuan forms are usually treated as subspecies of the highly polytypic Varied Sittella. Driven to the tops of the mountains during past glacial episodes, each form in New Guinea must have differentiated as a result of its geographical isolation from populations on other mountain ranges. Whether the morphologically intermediate forms represent hybrid zones can be resolved only by further fieldwork and analyses of DNA.

The Black Sittella was first discovered by A. Giulianetti while he was collecting for William MacGregor on Mount Scratchley, in the Wharton Range of south-east New Guinea, in 1896. Subsequent specimens were collected by H. A. Lorentz, in 1909, and by members of the American Museum Papuan Expedition, in 1933. Sadly, even many decades later, it remains a fact that very little is known about this species, which is confined to the mountains of central and south-east New Guinea.

### Morphological Aspects

Sittellas are small, somewhat dumpy, short-tailed oscines with a dagger-shaped or slightly upturned bill. The body length of the Varied Sittella ranges from 10 cm to 14 cm, and its weight from 8 g to 20 g, with the nominate race typically 10–14 g in weight. The Black Sittella is normally slightly larger and heavier. The wings are disproportionately long and broad, the tips of the folded primaries falling just beyond the tip of the tail; when the wing is spread, it shows a strongly curved trailing edge and distinctly fingered tips. The wing has ten primaries, the outermost of which is reduced, and nine secondaries, including three tertials and a vestigial innermost secondary. The short, squared tail has twelve rectrices. The legs are rather short, with scaling at the front (laminipantar scutulation), and the toes, especially the middle and hind toes, are long, the hind toe having the longest claw. True to their English vernacular names, the Black Sittella is largely black, with a bright pink face, and the Varied Sittella is highly variable in plumage, with streaked or unstreaked grey or brown upperparts, white or streaked underparts and, in Australia, a cinnamon-orange or white wingbar which is conspicuous in flight.

With five well-known subspecies in Australia, and four to six poorly known subspecies in New Guinea, the Varied Sittella is one of the most polytypic avian species in the Australo-Papuan region. In Australia the five subspecies differ in many ways, in-

cluding body size, the amount of streaking on the upperparts and underparts, the colour and extent of the wingbar, and the length and colour of the bill. Variation in these characters exhibits distinct and independent east–west and north–south trends. The two northern subspecies, for example, differ from the three southern ones in wingbar and bill characters, whereas the three eastern forms differ from the two western forms in the amount of ventral streaking. With the sole exception of the white-headed subspecies *leucocephala*, there is also sexual dimorphism, but it is confined to the head. Males have a black or brown cap and white, greyish or streaked eyebrows, lores and ear-coverts, whereas females invariably have the black extending to the face and chin and, in the subspecies *striata*, reaching the lower throat.

In New Guinea, however, the principal differences between subspecies are the head markings, and, given that the sexes differ in the same character, the validity of some subspecies is questionable. In contrast to the Australian subspecies, males of most Papuan races tend to be darker-headed than the females, having a black head with or without white scalloping, whereas the females' head is white or grey with dark streaks. An exception to this is the race *alba*, in which the male has a white head, but the full implications are uncertain because the female remains unknown for the present. Curiously, sexual dimorphism in the Black Sittella is evident only in respect of the bare parts, the eyes and legs of males being dark and those of females yellow.

Among Australian races of the Varied Sittella, the bill and wings of males are slightly longer than are those of females, but there are no constant differences between the sexes in weight, or in the length of the tarsus or tail. In addition, the hind claw of males, at least in north-east New South Wales, is more curved than that of females.

As pointed out by Parker, in 1982, the distinctively pale-spotted juveniles of sittellas bear an uncanny resemblance to those of several Australasian robins, particularly those of the genera *Microeca* and *Petroica*. Juvenile Varied Sittellas have white or pale buff feather tips, in the shape of a rose thorn, on the crown and mantle, and similar salmon-coloured, rufous-orange or creamy tips on the upperwing-coverts and flight-feathers. In the all-dark Black Sittella, likewise, juveniles have the feathers of the upperparts, underparts and wings tipped cinnamon-brown. The pale markings on the crown and mantle of the Varied Sittella are gradually moulted as the juvenile acquires its immature, or first basic, plumage, which it does within three months after fledging, but the pale-edged greater primary coverts, remiges and rectrices are retained for 5–10 months, until the first full adult moult.

With as many as eleven races in Australia and New Guinea, the **Varied Sittella** is markedly polytypic. The five Australian subspecies differ in the amount of streaking, the wingbar colour and extent, the amount of dark on the head, the length and colour of the bill, and slightly in body size. The New Guinea taxa differ primarily in head markings. In addition to all these variations, the species is sexually dimorphic in plumage and some measurements. Males have a slightly longer bill and wings, while Australian females, like this one, tend to have black extending onto the face and chin.

In contrast to the Australasian treecreepers, the foot of sittellas exhibits little structural modification for climbing. The pads on the sole of the foot are not reduced, the anterior "crests" on the proximal end of the tibiotarsus are not expanded, the toes and claws are relatively shorter, and the hind toe, or hallux, is curved dorsoventrally as on most perching birds, and not straightened as is typical of climbers. The curved hallux is an adaptation for perching on rounded substrates, such as twigs, as opposed to climbing on vertical surfaces. The third and fourth toes are united by the basal phalanx only. Like their northern ecological counterparts the nuthatches, but unlike the Australasian treecreepers, the sittellas are "reverse hoppers". In this climbing technique, the body axis is usually at an oblique angle to the trunk or branch, and the feet are held parallel, and widely spread. During climbing, either upwards or downwards, the bird proceeds in a series of hops, both feet being lifted from the substrate simultaneously. As the body is aligned obliquely, this action causes the bird to spiral around the trunk or limb. Thus, vertical movement on tree trunks is achieved by reversing the body axis at each hop.

As with the woodpeckers (Picidae), the front of the skull of sittellas bulges and there is an infolded naso-frontal hinge. In contrast to woodpeckers, and even nuthatches, however, the bill is strongly compressed laterally, and is therefore unsuited for the excavating of wood. The Varied Sittella has the tip of the tongue quadrifid (four-pronged) and unfringed, whereas that of the Black Sittella is bifid and with a short fringe, possibly for retrieving insects from clumps of epiphytic lichen (see Food and Feeding). Unlike those of nuthatches, the bristles around the base of the bill are weakly developed in the Varied Sittella; their near-absence in the Black Sittella may be an adaptation to avoid entanglement with epiphytic mosses and lichens.

### Habitat

Like the only other bark-foraging specialists in the region, the Australasian treecreepers, the family Neosittidae is confined to New Guinea and Australia, but is curiously absent from the great southern island of Tasmania. As the Varied Sittella is common in the mainland Australian state of Victoria, to which Tasmania was frequently connected during the Pleistocene ice ages, its absence

from the island is probably due to the lack of suitable forest habitat on it or its land-bridge to the mainland during these past cold, dry glacial epochs. Certainly, in today's wetter climate there is no shortage of suitable habitat on Tasmania, where various honeyeaters and other species have filled the bark-foraging niche. Perhaps, in addition, an impoverished bark-dwelling arthropod fauna contributed to the demise of any sittellas or treecreepers that may have been marooned on Tasmania before its final separation from the mainland, some 5000 years ago, with the opening up of the 200-km-wide Bass Strait.

In Australia's tropical north, however, Varied Sittellas are present on the Tiwi Islands, comprising the islands of Bathurst and Melville, a combined area of about 5000 km<sup>2</sup> and situated some 27 km from the nearest mainland, yet they are absent from Groote Eylandt, which covers about 2300 km<sup>2</sup> and lies approximately 40 km from the mainland. Both island areas were joined to the mainland during the last ice age, until approximately 6000 years ago, and both have ample suitable woodland habitat. Clearly, the Tiwi Islands are larger and closer to the mainland, but the flight of sittellas is characteristically weak (see General Habits) and it is doubtful that they could cross a sea barrier of even 27 km. Instead, their absence from Groote Eylandt may be related to the species' apparent scarcity on the adjacent mainland.

The evolution of five distinct subspecies that replace each other geographically around the continent strongly suggests that the range of the Varied Sittella in Australia was fragmented rather recently, with insufficient time for the forms to evolve into separate species. The most likely scenario is that populations were isolated from each other during the last glacial epoch, about 25,000–10,000 years before present, confined to moist refuges around the continent's periphery, and separated by large expanses of grassland or sparsely covered low woodland, both inland and on the crest of the Great Dividing Range, which was possibly 200 m higher than it is today. Progressive amelioration in the climate allowed these differentiated forms to spread from their past refugia, particularly in the case of the two western subspecies, which must have spread over 1000 km eastwards, but were presumably already preadapted to drier woodlands. Finally, the partial vacuum in central Queensland until the recent past allowed all five formerly isolated subspecies to meet and hybridize in this region, which, owing to the lack of any marked

The **Varied Sittella** is a sociable species, living in groups of up to 30 birds.

Flocks often split into subgroups for the breeding season, a social system similar to that of co-operatively breeding thornbills (*Acanthizidae*) that often share sittella habitat. This sittella quintet is huddling together at a typical roost site on a thin horizontal branch. Roosting behaviour reflects and probably reinforces the group's social relations, being highly ritualized and following the dominance ranking within the group. The breeding male leads the group to the roost-site, and usually occupies the vulnerable outermost position, where he appears to act as a look-out.

[*Daphoenositta chrysoptera pileata*, Little Desert National Park, Victoria, Australia. Photo: Peter Fuller]

environmental gradients, permits the back-crossing of hybrids with their parental gene pools.

In Australia today, the Varied Sittella is found in a broad variety of habitats, ranging from the low acacia (*Acacia*) shrublands dominating the arid interior to very tall wet eucalypt (*Eucalyptus*) forests of the south-east and south-west. Paradoxically, the one form of vegetation that it avoids in Australia, rainforest, is its exclusive habitat in New Guinea. On this exceptionally mountainous tropical island, however, neither sittella species occurs in the lowland rainforests. Here, the Varied Sittella inhabits the highland rainforests dominated by oak (*Castanopsis*) and laurel (*Lauraceae*) at around 1000 m above sea-level, and the mossy montane rainforests to as high as 2600 m, along the entire length of the central cordillera running east-west through New Guinea, including the ranges of the Vogelkop Peninsula in the west and several isolated ranges in the east. Its habitat and altitudinal range overlap slightly with those of the much more restricted Black Sittella, which is confined to moss-covered upper montane rainforests of New Guinea at elevations from 2000 m to 3600 m.

### General Habits

Being both highly sociable and seemingly hyperactive, sittellas make entertaining subjects for study. Their restless behaviour doubtless frustrated early collectors and subsequent workers searching for the Black Sittella in the remote and rugged terrain of New Guinea's highest mountains. J. M. Diamond reported that this species spends only a few minutes in a tree before flying off, usually out of sight. Although Diamond encountered the Black Sittella "always in flocks of three to five birds", A. L. Rand reported that flocks numbered six to ten individuals, adding that they "move about quickly through the forest". These descriptions apply equally well to Varied Sittellas in Australia, for which flock sizes of up to 30 have been reported, although only four of 44 groups observed in north-east New South Wales and central Queensland contained more than seven individuals. The mean group size in these regions was 5 and 4.7, respectively; simple pairs were recorded in 20% of cases. Complicating the determination of the sizes of groups, however, is the dynamic nature of their composition, as demonstrated in a study in north-east New

South Wales, where the size of four groups varied over the year from two to nine individuals, the average being 5.4 birds.

Encounter rates with sittellas are often low, this being due to their typical habit of gathering into compact, rapidly moving flocks, as well as their low population densities and presumably large home ranges in many sparsely wooded habitats, such as open savanna or shrubland. This may give the impression that the species is highly mobile, and, indeed, many have claimed that sittellas either are nomadic or undertake small-scale movements. Long-term surveys in eucalypt forests of eastern Australia, however, have shown that Varied Sittellas are sedentary, with densities typically ranging from 0.1 to 0.6 birds per hectare. Moreover, the flight of sittellas is characteristically weak and undulating, with long glides between flapping, and this makes it unlikely that they carry out long-distance movements. Unconfirmed reports of emigration and immigration at various localities, mostly in semi-arid regions, may also be related to temporal changes in their social organization, as large noisy flocks are obviously more conspicuous than pairs or small groups.

Sittellas appear to have a complex and dynamic social organization that involves two or more tiers of groups, subtle dominance hierarchies and, perhaps, a plural co-operative breeding system. Although there has been no intensive study of the social organization of these species, opportunistic observations of a local population of Varied Sittellas in north-east New South Wales, which contained several colour-ringed individuals, suggested the existence of four "clans" each of 8–12 individuals, each clan ranging over 13–20 hectares. While there was slight overlap among these home ranges, interactions between clans along borders suggested territorial defence, albeit infrequent and not particularly hostile. These clans split up into smaller units at the beginning of the breeding season and reunited during the non-breeding season, a social system similar to that of co-operatively breeding thornbills (*Acanthizidae*), which often share the sittellas' habitat. For example, one clan of eight Varied Sittellas split into two quartets, one of which broke up into pairs at the start of the breeding season; these pairs, however, after unsuccessful nesting attempts, coalesced for subsequent breeding attempts, and, finally, amalgamated with other members of the clan at the end of the breeding season.

Population sex ratios appear to be biased towards males, this being probably due in part, at least, to higher dispersal rates among

females. Among 43 adult and subadult Varied Sittellas collected from 14 or 15 groups encountered within far north-east New South Wales, males outnumbered females by 2.3 to 1. Three quartets and one sextet contained only one female each, while another sextet contained two females. Sixteen randomly collected individuals from groups in another part of the same region displayed a similar skew of 2.2 males to 1 female, and trios invariably comprised two males and a female. Several lines of evidence from the north-east New South Wales study site suggest that pre-breeding dispersal involves mainly females, males being more strongly philopatric. In one group, an unringed adult female joined and became the breeder within only six days of the death of the previous colour-ringed breeding female; within one month the new breeder expelled the 11-month-old daughter of her predecessor, a process that included repeated attacks as the younger female attempted to join the group at its roost. Another adult female which joined the group was repeatedly chased away by the breeder as it attempted to feed the latter's nestlings. In another region, the only solitary Varied Sittellas located turned out to be females. In contrast, non-breeding males at two sites remained for at least two years in the territories where they were ringed. Of two siblings colour-ringed as nestlings, the male remained in his natal territory for at least 13 months, whereas his sister disappeared soon after the start of the next breeding season, about nine months after fledging.

The activities of group-members are highly synchronized and co-ordinated, especially when flying between trees. Flight to the next tree usually takes place only after at least one individual, probably a dominant one, has given "rallying calls" (see Voice). If a subordinate individual flies from a tree prematurely, particularly in open country, it will circle back and wait until the remainder of the group is ready to fly. The group-members then fly as a cohesive unit until the next tree is approached, whereupon they spread out to forage over all parts of the tree. As all members forage simultaneously, there appears to be no sentinel system. Resting and preening are also carried out by all group-members simultaneously, each individual usually separated by 1–5 m from the others, unless engaging in mutual preening. This high level of co-ordination within the group, however, can at times seem maladaptive, as when many birds queue beside nests, anxiously and noisily waiting their turn to add building material or to feed the young.

Typically for social birds, sittellas frequently engage in mutual preening, or allopreening. This behaviour is usually seen after sittellas have spent a few minutes in self-preening. One individual

sidles up to another and preens it for a few minutes, and the other then reciprocates. Such behaviour frequently involves the breeding male and the breeding female, but mutual preening also involves breeding and non-breeding adult males, and adults and juveniles, as well as two juveniles, but apparently does not occur between adult females. In addition, juveniles are often allopreened simultaneously by two adults, one on each side; in seeking such attention, they sometimes wedge themselves between two preening adults. Because juveniles preen adults, and non-breeding males preen breeders, the direction of allopreening provides no clues as to the dominance ranking of individuals. Indeed, as sittellas are rarely hostile towards one another, it is difficult to discern a social hierarchy among group-members, at least during the day.

Although it has been known since at least 1967 that Varied Sittellas roost communally, it was not until 1980 that a detailed 12-month study of a colour-ringed group of 5–7 individuals revealed the significance of roosting behaviour in reflecting and probably reinforcing intra-group social relations. On a total of 120 nights the group used as roosts only 13 trees, scattered over the entire territory of 20 hectares, and, although it utilized one site continuously for at least 19 days, at other times it switched roost-sites frequently and unpredictably. The most frequently used roost-sites ranged in height from 9 m to 16 m, and almost all were in the upper half of the tree.

The birds always huddled at the base of a thin horizontal or slightly upwardly inclined dead branch, about 2–3 cm in diameter, on a living or dead eucalypt, with the innermost individual touching the adjoining branch, which in most cases formed a roof over the roost branch. When settled, all birds faced the same direction, each leaning head downwards and tail upwards at an angle of about 45 degrees, until it was ready to sleep, at which point it assumed a more vertical stance, with the head tucked backwards. The distinctive pre-sleeping posture seems adaptive in facilitating a quick launch. At the first sign of danger, the group "explodes" from the roost-site, individuals fleeing in all directions, making pursuit of any one bird almost impossible for a predator. The intimate physical contact between individuals that is afforded by huddling allows a quicker reaction than would be the case if the birds were spaced out.

In contrast to their behaviour when foraging, sittellas did not arrive at the roost-site simultaneously but, instead, came in at intervals of 30–60 seconds, apparently so as no to attract the attention of potential predators. After the first two settled at the base of the branch, the other group-members usually flew to the

*Sittella* vocalizations are simple, as there is no need for a wide vocal repertoire where group-members live close together and have a clear hierarchical rank. Neither *sittella* sings. The **Varied Sittella** has five distinct calls, each with a specific purpose: birds give a soft contact call when foraging; a "rallying" call marks the group's movement between trees; the incubating female and young chatter to beg for food; subordinate birds near a dominant individual, and females about to copulate, utter a wheezy "submission" call; and when startled, sittellas give a shrill alarm call.

When foraging on trees, the Varied Sittella ascends trunks in a spiral, or descends them head first. The species climbs rapidly along the uppersides of branches, peering one way then the other, flicking open a wing to flush out cryptic prey. The commonest foraging techniques involve gleaning, or scaling the bark surface. In the latter, the bird wedges its long mandible under bark, then pivots the bill to dislodge the bark. Birds will also probe crevices, as here, or search underneath peeling bark, and occasionally sally for aerial insects.

[*Daphoenositta chrysoptera*, Australia.

Photo: Roland Seitre]

tip of the branch, hopped back towards its base, and squeezed up between any two individuals already present, gradually forcing the outer bird or birds farther along the branch. On more than one short branch, this caused the outermost individual to fall off the end. The sittellas settled to roost much earlier, and awoke later, than all other passerines observed in the study area. The mean monthly time of roosting varied from 2 minutes before sunset, in December, to 25 minutes before sunset, in July. This was 26 minutes earlier, on average, than the slightly smaller, communally roosting Striated Thornbill (*Acanthiza lineata*). Despite being the earliest to settle at their roost-site, however, the sittellas were not necessarily the first asleep, nor the first awake. At least one individual stayed awake until darkness had fallen, and the minimum elapsed time from the moment when the last bird arrived to when the last one fell asleep varied from 23 to 48 minutes, with an average of 36 minutes. On four mornings, the Striated Thornbills and nine other species were actively foraging 3 minutes before the sittellas awoke, yet the sittellas did not depart from their roost-site until 7–10 minutes later.

Amazingly, the order in which certain sittellas arrived at the roost, their positions within it and even the order in which the birds went to sleep remained highly constant from night to night. The breeding male led the group to the roost-site, and others rarely moved towards the site while he was still foraging, or, if they did, they soon lost interest. He also initiated departure when the site was abandoned for another site. The breeding male was the first to arrive, and the non-breeding male the second, on 38 of 45 nights when arrival of individuals was monitored. The non-breeder preceded the breeder on the remaining nights, but on each occasion he flew off as soon as the latter arrived. The non-breeder always approached the breeder while holding its head lowered and with its wings quivering, clearly indicating its subordinate status. The third group-member to arrive was most often the breeding female, as was the case on 30 of the 45 nights, but she was preceded by her son on most of the remaining nights. The last to arrive was usually the immature or non-breeding adult female. As the adult males were the first two to reach the roost, they almost invariably occupied the end positions of the huddle, the breeder in the outermost position in 72% of cases. The breeding female was most often beside her mate, while the youngest birds were usually in the middle. This configuration, with males in the end positions and young in the centre, was observed also at another locality where sittellas had been colour-ringed for individual identification.

While huddling behaviour is generally thought to have a thermoregulatory function, its major role for roosting sittellas may be that of ensuring safety, as well as reinforcing social status. The behaviour of sittellas on arrival at the roost is highly ritualized, reflecting dominance ranking within the group. The final configuration, and the order of sleeping and waking, conferred protection on the young and the breeding female. Reflecting their lack of parental responsibility, the immature male and the immature female, from 2 to 6 months post-fledging, were always the first two individuals to fall asleep, the female being the first on 28 out of 36 nights. Significantly, the outermost male was the last to go to sleep on all but two of 16 nights, whereas the innermost male was sometimes among the first asleep. The outermost male appears to act as a guard for the group, staying awake for up to 48 minutes after settling. Only the outer end of the roosting huddle afforded an almost unobstructed view of the surroundings, whereas the view of the innermost male was always partly obscured by the branch adjoining the roost branch, as well as by the individual bird roosting alongside. There would seem to be little benefit in the outermost male staying awake for up to 48 minutes after settling unless there was some risk of attack from a predator. The risk of predation also explains the early roosting time of sittellas, the staggered, rather than simultaneous, arrival of individuals at the roost, and the distinctive pre-sleeping posture.

## Voice

Given that most sittellas probably remain with their natal group or clan, and that group-members stay close together throughout

the day, each having a clear dominance rank within the group, there is little need for long-distance calls or a sophisticated vocal repertoire. The vocabulary of sittellas is therefore relatively simple, and the most frequently uttered calls are concerned with co-ordination of group activities.

Of the five vocalizations known for the nominate race of the Varied Sittella, the most commonly heard is the monotonous "chip" contact call, which is repeated frequently during foraging and flying. The rallying call, a drawn-out double whistle of upward-inflected notes, signifies an individual's intention to fly and apparently serves to synchronize the flight of all members of the group, so that there are no stragglers. As other group-members respond with rallying or contact calls, the noise of the group often rises to a crescendo just prior to take-off. During the breeding season, the chattering food-begging calls are given incessantly by the incubating female, as well as by fledglings and dependent juveniles, when receiving or begging for food. These calls resemble a rapidly repeated, high-pitched version of the contact call, and are invariably accompanied by wing-quivering.

When subordinate adults or juveniles approach a dominant or older individual, they often crouch and quiver the wings, and occasionally emit a soft, wheezing "Submission call". This vocalization is given also by the breeding female prior to copulation with her mate. When suddenly startled by a potential aerial predator, sittellas utter an alarm call similar to the food-begging call, but shriller and more sustained. All group-members then freeze in the head-down position, the body oriented parallel to the branch or hanging upside-down under the branch.

The Black Sittella of montane New Guinea appears to have similar vocalizations to those of its more widespread congener. Its incessant contact calls are described as faint, sweet, "sucked-in" notes, which are louder when given in flight than when uttered from a perch. Black Sittellas also give faint chattering calls when two individuals interact.

## Food and Feeding

Sittellas eat a wide variety of insects and other arthropods. Of 992 items found in the stomachs of 59 Varied Sittellas from north-east New South Wales, over a third, 36%, were small adult beetles (Coleoptera), mainly of the families Curculionidae (weevils), Chrysomelidae (leaf beetles), Coccinellidae (ladybugs) and Elateridae (click beetles). Bugs (Hemiptera) and spiders (Araneae)

together comprised roughly a further quarter, respectively 14% and 13% of items. The larvae of beetles, including those of the families Cleridae and Melyridae, and of moths (Lepidoptera), including geometrids, comprised about 33% of the total prey biomass in the stomachs, despite the fact that they constituted only 17% of the total number of items. Other taxa recorded in stomachs of Varied Sittellas from here and elsewhere were grasshoppers (Orthoptera, including Gryllacrididae), craneflies (Tipulidae), cockroaches (Blattodea), wasps and bees (Hymenoptera), termites (Isoptera), lacewings (Neuroptera) and pseudoscorpions (Pseudoscorpiones).

In stark contrast to the other, larger bark-foraging specialists of the region, the Australasian Treecreepers, sittellas consume relatively few ants (Formicidae). Ants constituted a minor proportion, just 7%, of the items found in the stomachs of Varied Sittellas from north-east New South Wales, and were found in only a third of these specimens. Moreover, only one of the faecal samples from ten mist-netted individuals contained ants. In south-west Western Australia, however, faeces from four Varied Sittellas contained mostly beetles and ants, which accounted for, respectively, 81% and 12% of items. Apart from the obvious disparity between these two regions in the relative importance of beetles, prey sizes indicate that the diet of sittellas may vary geographically: at the Western Australian site, 83% of prey items were estimated to be less than 4 mm in length, whereas the mean lengths of the three major taxa constituting 63% of items in New South Wales ranged from 4 mm to 10 mm. As may be expected from the shorter bill, sittellas ate significantly smaller beetles and spiders than did co-occurring Red-browed Treecreepers (*Climacteris erythrops*), although the two species did not differ in the size of larvae and bugs that they took.

The importance of larvae in the diet of sittellas was confirmed by sightings of prey items in the north-east New South Wales studies. Of 70 prey items observed, 87% were larvae. Although beetle grubs were more numerous than were moth caterpillars in stomachs, the latter predominated in direct observations, presumably because of their generally larger size. In tall mulga (*Acacia aneura*) shrublands in central Australia, 16% of 43 observations of feeding sittellas involved caterpillars of geometrid moths taken from mulga foliage, but these larvae were unusually abundant at the study site. Although little is known about the diet of the Black Sittella in the montane rainforest of New Guinea, one individual of this species was observed as it ate a larva 3 cm long, and stomachs of specimens contained caterpillars and a spider.

Possibly the most accurate description of the typical foraging behaviour of sittellas was provided by Diamond and concerned, rather ironically, the rarely seen Black Sittella.

"It hops rapidly along a branch at about 300 mm per second, leaning over and peering first to one side then the other, and flits off to another branch. While it occasionally clings to the underside of a horizontal branch or goes up a vertical one, much more often it remains on the upper side of horizontal branches."

This account applies equally well to the Varied Sittella, which in 7-8 hours of foraging observations in north-east New South Wales spent 41% of the time hopping, mostly in this zigzag fashion, along branches away from the tree trunk, and 17% moving back towards the trunk. As it leans over the side of the branch, it often quickly flashes and gently quivers the wing furthest from the branch, probably to flush cryptic prey by frightening it with the sudden or flickering motion, or the boldly contrasting colour pattern in the wing. After reaching the end of a dead branch, the sittella will often circle the tip to scan any broken parts, and then turn around and hop quickly back towards the trunk, without pausing. On tree trunks, sittellas at the above site spent a similar amount of time descending, head first, as they did ascending, respectively accounting for 19% and 23% of timed observations. Both species of sittella often hang upside-down from branches while probing the bark or moss for insects. Allegedly, New Guinea races of the Varied Sittella frequently crawl on the underside of branches, but such behaviour, as it is very rare or non-existent among Australian populations, may be peculiar to those inhabiting rainforest, where an abundance of lichens, mosses and other epiphytic plants provide ample irregularities to grip while the bird is upside-down.

Varied Sittellas in north-east New South Wales climb at an average speed of 60 mm per second, much slower than the speed reported by Diamond for the Black Sittella. The mean distance flown between branches was 88 cm. In the intensive study in New South Wales, it was found that Varied Sittellas spent, on average, 58 seconds on each tree, although in New Guinea both species purportedly spend a few minutes in each tree before flying off. It seems unlikely, however, that sittellas in New Guinea spend three times longer on a tree and yet climb five times faster than do those in Australia.

Sittellas feed mainly in the canopy, but they do occasionally descend to the lower portions of tree trunks or forage on stumps and logs. Foraging heights depend to some extent on the canopy height. In the eucalypt forests of north-east New South Wales, where the canopy height was around 20 m, some 6-13% of observed foraging attempts were made at heights greater than 15 m, whereas in south-east New South Wales, where the canopy rose to more than 30 m, 36% of foraging heights were above 14 m. In contrast, in low banksia (*Banksia*) woodland in south-west Western Australia, 96% of observed foraging was at 2-6 m, and in mulga shrubland in central Australia the mean foraging height was only 2.4 m.

In studies in eucalypt forests of eastern Australia, Varied Sittellas exhibit a distinct foraging preference for the highly fibrous-barked stringybarks, largely ignoring the many other eucalypt species, which constituted at least half of the trees and were predominantly smooth-barked. In New South Wales, for example, stringybarks accounted for 80% of 776 trees visited in the north-east of the state and for 89% of 357 trees in the south-east. Nevertheless, in wandoo woodlands of Western Australia, where the smooth-barked wandoos *Eucalyptus wandoo* and *Eucalyptus accedens* form almost pure stands, 89% of 114 observed foraging attempts were on these two species, suggesting that the tree-species preferences of sittellas vary geographically, depending on the available bark types and perhaps their arthropod fauna. In the monsoon tropics of northern Australia, too, sittellas appear to be at least as common in woodlands dominated by the predominantly smooth-barked Darwin woollybutt (*Eucalyptus miniata*) or the entirely smooth-barked salmon gum (*Eucalyptus tintinnans*) as they are in open forests dominated by the entirely rough-barked Darwin stringybark (*Eucalyptus tetradonta*). In eastern Australia, Var-

*Sittellas exclusively eat insects and other arthropods. Over a third of the diet of the Varied Sittella comprises beetles. Bugs and spiders together make up a quarter, and the larvae of beetles and moths form a third by weight; cockroaches, wasps and grasshoppers are also taken. The shorter bill of the sittella compared with that of the partially co-occurring Red-browed Treecreeper (Climacteris erythrops) means that it captures significantly smaller spiders and beetles than its fellow bark specialist. Unlike the Australasian treecreepers, sittellas consume few ants.*

[*Daphoenositta chrysoptera pileata*, Australia.  
Photo: Roland Seitre]

Facing downwards on a vertical trunk, this Varied *Sittella* may have just flushed out its prey by flicking open a wing. Sittellas feed mainly in the canopy. Like fellow bark-foragers such as Australasian treecreepers (Climacteridae), sittella sexes differ in preferred foraging heights and substrates. This may relate to sexual dimorphism in bill length and hind-claw curvature. The longer-billed male is better adapted to probing crevices in rough-barked trees, while his more strongly curved hind-claws give him the good grip necessary to descend head first to the lower trunk.

[*Daphoenositta chrysoptera chrysoptera*, Warriewood, Australia. Photo: Nevil Lazarus]

ied Sittellas display a constant predilection for dead branches, although this varies with eucalypt species: on smooth-barked boxes, gums and ashes 42–80% of foraging was on dead branches, whereas on stringybarks the figure was only 25%.

Like many bark-foraging birds, including the forest dwelling White-throated (*Cormobates leucophaea*) and Red-browed Treecreepers sharing their habitat, sittellas exhibit marked sexual differences in foraging behaviour. In north-east New South Wales, male Varied Sittellas of the nominate race spend significantly more time at lower levels and on rough-barked trunks and large boughs than do females, the latter concentrating instead on predominantly smooth-barked branches and twigs, which are most abundant at higher levels. In one colour-ringed group of four adults and two juveniles aged 2–3 months, the mean foraging heights of the two adult males were 10 m and 11 m, whereas those of both adult females were around 14 m; as the breeding male tended to forage at higher levels than those exploited by the non-breeding male, it is possible that he was guarding the breeding female from his potential sexual rival. The two juveniles, one of each sex, foraged at intermediate levels, and, as they did not differ in their foraging heights, it is possible that the sexual differences apparent between adults are learned, rather than being innate. Alternatively, the foraging heights of these juveniles may be optimal in terms of provisioning and protection from predators by adults of both sexes.

Sexual differences in preferred substrates, and hence in vertical heights, may be related also to sexual dimorphism in bill length and hind-claw curvature (see Morphological Aspects). The longer-billed male seems better equipped to probe into the deep fissures on the trunks and boughs of stringybarks, and its more strongly curved hind claws would be advantageous for gripping the surface when descending trunks head first.

Intersexual foraging segregation may alleviate intraspecific competition for food, which could be critical for bark-foragers in search of scarce cryptic prey, but there are no obvious differences between the sexes in the types and size of prey that they select. Instead, foraging segregation of the sexes in the case of the sittellas seems to have evolved in response to their sociality, as all members of the group (see General Habits) invariably forage in one tree simultaneously. Separation of the sexes reduces the chance of hostile interactions between group-members and, further, reduces the probability of an individual wasting its time

by foraging in areas that have already been investigated or exploited by another, thereby increasing its foraging efficiency. The extent of sexual differences in foraging behaviour may be expected to vary regionally, depending on the range of tree heights and bark types available, yet vertical segregation of the sexes occurs also among Varied Sittellas of the race *leucoptera* in the Darwin region of north-west Australia, about 3000 km distant from the above-mentioned nominate population, indicating that the phenomenon may be widespread.

The major foraging techniques of Varied Sittellas are glean-ing at the bark surface, which accounted for 53–99% of observations in nine studies, and probing into crevices or curled strips of peeling bark, which represented 12–47%. In addition, these birds occasionally sally for aerial insects or web-spinning spiders, and they even glean from foliage; indeed, foliage-gleaning made up 16% of foraging in one study. A further common technique, but one as yet unquantified, is that of scaling or flaking, whereby the bird dislodges a flake of bark to expose hidden prey; it achieves this by wedging the lower mandible under the bark, and then pushing the head forwards and upwards, using the tip of the bill as a pivot.

Unlike the Australasian treecreepers, sittellas regularly use their feet in order to hold a prey item on to the branch while preparing it for ingestion, or to anchor curled strips of bark while probing them. As is the case with many species of parrot (Psittaciformes), the left foot is used significantly more than is the right one, evidence of functional asymmetry in the brain; in one study, Varied Sittellas used the left foot 32 times and the right one 16 times. Before swallowing a large caterpillar, the bird whips it several times across the branch while holding it in the bill; it then extracts the viscera while pinning the prey down by the foot, and finally discards the viscera by wiping it across the branch. The hard wing shields (elytra), head and thorax of beetles are torn off in a similar manner.

As a final point of interest, the Varied Sittella has been reported once as using tools, although such behaviour must be either extremely rare or restricted to certain populations. Three individuals of the nominate race allegedly utilized small match-stick-sized strips of wood or twigs in order to extract wood-boring larvae; they poked the strip into holes in branches, and even carried the implement for a short distance before repeating the performance.

## Breeding

Co-operative breeding is possibly obligatory for successful reproduction by the Varied Sittella. Of 23 nests of this species observed in north-east New South Wales, only two were attended by simple pairs, and neither of these succeeded in producing offspring. Breeding groups usually comprise a breeding pair and one to seven helpers, which assist in the construction of the nest, the feeding of the incubating female, the feeding of the young and the removing of their faecal sacs, and the defence of the nest.

Evidence for plural co-operative breeding, in which two or more females within a group engage in reproduction, derives from several sources. As long ago as 1917, P. A. Gilbert had watched four adults as they fed young at one nest, after which they flew off to collect food for young in another nest about 90 m away. In north-east New South Wales, a clan of twelve individuals divided into at least three breeding groups, and, although the breeders in these groups occupied exclusive areas, two colour-ringed non-breeders shared two of these areas and concurrently helped both groups in their breeding attempts. In south-east New South Wales, two nests separated by 500 m were both attended by up to five individuals; as the number of attendants at each varied demonstrably during the day, however, the observer of these nests speculated that only one roving clan might have been involved.

Finally, nest-sharing, in which two females lay eggs and incubate or brood in the same nest, side by side, has been recorded at least twice, indicating a level of tolerance among breeding females that is usually absent in non-plural co-operative breeders. Such instances also suggest the possibility of polygynous matings.

Although observations of colour-ringed Varied Sittellas in north-east New South Wales indicate that social monogamy is the rule, several instances of sexual rivalry among members of one group suggest that there is potential for extra-pair copulations. Immediately before the completion of one nest, the breeding male was seen repeatedly to supplant and chase the other two males in his group whenever they approached the nest and the breeding female, possibly guarding her to avoid being cuckolded. Moreover, in two seasons, just prior to nesting, the breeding female repeatedly attacked non-breeding females as they attempted to join the roost.

That Varied Sittellas are multi-brooded is clear from several reports of late nests at which juveniles 8 weeks old provided help in nest construction or in the feeding of their younger siblings. In north-east New South Wales, the species lays eggs in all months from August to January, with peaks in late September and late November, probably coinciding with first and second clutches. In the tropical north of Australia, however, the breeding season appears to be broken by the first major rains, as clutches have been recorded during the middle to late dry season, from July to October, as well as during the latter half of the wet season, from February to April.

Although neither sittella species in New Guinea has been observed while nesting, Black Sittellas had enlarged gonads in both August and May. This suggests either a biannual breeding season, as in many species in the monsoon tropics of Australia, or year-round breeding, which seems feasible in view of the constantly wet conditions of the species' equatorial montane habitats.

The nest of the Varied Sittella must surely be one of the most exquisitely camouflaged of all bird nests. A deep cup on the inside, it appears cone-shaped or even tube-shaped on the outside, and is usually built at the base of a two-pronged fork of a near-vertical branch, although some nests are built on top of a knot or small kink in a more horizontal branch. The nest is composed largely of small pieces of finely shredded bark, occasionally mixed with fur, plant down or dry lichen, and copiously bound with spider web and egg sacs. Externally, it is decorated with flakes or short strips of bark laid vertically, or with lichen, depending on the colour and texture of the supporting branch, which it invariably closely matches. The top of the nest is left jagged, with small pieces of bark or lichen protruding upwards, giving the appearance of a broken-off limb. Internally, it is lined with soft bark, spider egg sacs, moss or lichen, and occasionally with wool, fur or feathers, the resultant colour pattern at least sometimes camouflaging the blotched eggs.

Of 57 nests of Varied Sittellas found in north-east New South Wales, 95% were built on dead branches, and 88% were in stringybarks, mostly of the species *Eucalyptus macrorhycha*, and always in the upper half. Elsewhere, nesting trees include she-oaks (*Casuarina* or *Allocasuarina*), acacias and paperbarks (*Melaleuca*). The height above ground at which nests are built varies from 6 m to 25 m, with averages of 11 m and 13 m at two localities. In some places, certain nest trees, or even nest branches, are reused over several consecutive seasons, and in at least one reported case a nest-site was reused within the one season, following a successful earlier brood. Although the building of the bulk of the nest requires only 5–9 days, the internal and external lining may take up to ten more days to complete. Materials from recently abandoned nests are used in the construction of new nests. The time taken to construct the nest may depend on the number and skills of the available helpers, which sometimes include juveniles, as young as 7 weeks post-fledging, from a previous brood. At one nest, the percentage contribution in terms of building visits made by the primary male and the primary female was 21% for each; that of the non-breeding male was 25%, and the respective figures for the yearling female and male were 18% and 11%. An individual, if it came to the nest "empty-handed", would often sit inside, adjusting the exterior with the bill and moulding the interior of the nest by means of trembling body movements. Despite the length of time taken in the building work, many nests are abandoned soon after completion, apparently in response to disturbance by a potential predator. In one study, up to 25% of nests were abandoned in this way.

The primary male feeds the primary female prior to, and during, egg-laying, which begins 4–12 days after the nest has been completed; whether the helpers feed her at this stage is not known. Copulation is a simple affair, the female crouching over a branch, with wings quivering, and the male spiralling around her several times, before he mounts her.

The clutch of the Varied Sittella usually comprises three eggs, but clutches of two eggs are also common. All nine accessible nests at one site in north-east New South Wales had three eggs, and 24 of 39 nests in the Birds Australia Nest Record Scheme held three eggs, while twelve of the remaining 15 had two eggs. One reported clutch of five eggs, and another of seven, may have been the result of two females laying in the same nest. The eggs of this species are bluish-white or greenish-white, boldly spotted and blotched with black, grey, lilac, olive and/or sepia, these markings concentrated mostly around the centre or at the larger end, and often forming a defined zone. They are reminiscent of those of certain flyrobins and monarchs of the respective genera *Microeca* and *Myiagra*. As with so many other Australian passerines, the eggs are usually laid at 48-hour intervals, although those in one clutch of two eggs were apparently laid approximately 24 hours apart. Incubation begins with the laying of the second egg, which results in asynchronous hatching and fledging in at least some three-egg clutches. Except in the rare instances when two females share a nest, only the primary, breeding, female is responsible for the incubation of the eggs and the brooding of the chicks.

Given its body size and exposed nest, the Varied Sittella has a surprisingly lengthy incubation period, as long as 19–20 days, this perhaps the consequence of its specialized foraging niche and a relatively scarce food supply. Other Australian bark-foragers are less specialized in their choice of prey and foraging substrates; the Australasian treecreepers, for example, eat a large number of easily procured ants to compensate for the low abundance or patchiness of other bark-dwelling prey. Scarcity of suitable prey also explains the necessity for the primary male and all available helpers to feed the incubating female as often as twice a minute, but more usually 3–10 times per hour. Depending on the time of the day, the female sits for 55–92% of the time, the average at different nests varying from about 60% to 79%, during bouts lasting 7–56 minutes. The averages of incubating bouts at two nests with three eggs were 20 and 22 minutes. Despite receiving most of her food either on the nest or within a metre of it, the female leaves the nest for an average period of 10 minutes, but up to 36 minutes, during which time she begs for food, with constant shrill chattering and with wings quivering, as she scuttles

The **Varied Sittella**, like many Australasian passerines, breeds co-operatively. The bird descending the branch to feed the incubating female may be either the latter's male partner or a helper. In the sittella breeding system, a central breeding pair is assisted by 2-4 non-breeding adult auxiliaries. These helpers assist in the construction of the nest, the feeding of the incubating female and young, the removal of faecal sacs and the defence of the nest. Helpers at a second brood in the breeding season may include two-month old juveniles from the first brood. The female incubates on an extremely well-camouflaged nest. On the inside it is a deep cup, but the outside is cone-shaped. Usually placed at the base of a two-pronged fork, as here, the nest is constructed from small pieces of bark, sometimes mixed with fur, plant down or lichen, and bound with spider web. Outside, it is decorated with short, vertical strips of bark or with lichen to match the colour and texture of the nest tree. The top of the nest has protruding bits of bark or lichen to make it look like a broken-off tree limb. The bulk of the nest takes only 5-9 days to build, but the decoration and lining can take a further 10 days, depending on the number of helpers. Most nests are built relatively high in the respective tree, and nest trees may be reused in consecutive breeding seasons.

At 18–20 days, the nestling period of the Varied Sittella is as prolonged as its surprisingly lengthy incubation period. All members of the group feed the nestlings; here we see a female feeder on the left and a male on the right. At 17 days old, the chicks take their first tentative steps outside the nest, then rapidly return to safety, but within three days they are actively flying around with the group. This does not, however, mark the end of the parents' responsibilities. Juvenile sittellas remain dependent on their parents for at least 60 days after fledging. This unusually protracted period may be related to the species' specialized niche and the time required for juveniles to learn sex-specific foraging behaviour.

[*Daphoenositta chrysoptera pileata*, Rupanyup, Victoria, Australia.

along branches close to the nest. Yet she also sometimes gives rallying calls (see Voice) while sitting on the nest, presumably signalling her intention to leave and her demand for food. One female was observed to call continuously for 25 minutes during an incubation session of 35 minutes.

Nestlings of the nominate race of the Varied Sittella are well covered in pale grey down, which is retained for at least eight days, at which time the eyes begin to open and the wing quills begin to erupt. The bill is blackish, the rictal flange, or gape, is pale cream, and the legs are flesh-brown. As with the incubation period, the nestling period is long, lasting for 18–20 days. The female broods the chicks for 60–75% of the time during their first day after hatching, but this decreases over the following eight days, until she stops daytime brooding after a period of 9–14 days. At night, however, she broods for up to 16 days after the hatch. All members of the group, except perhaps unrelated females, feed the young and remove their faecal sacs. During the first week, at least, the primary male and helpers often deliver their offering to the brooding female, which passes it to the nestlings or, in some cases, eats it herself; in one study, the female consumed 24% of such food deliveries. At one nest with three chicks, the contribution by the primary pair was 58%, of which 35% was by the male, while the remaining three group-members, consisting of a non-breeding adult male and a juvenile of each sex, each contributed 10–18% of the total feeds. The mean provisioning rates vary from 12 to 20 feeds per hour, although at one nest with at least five attendants 46 feeds were observed in 63 minutes of observation. In their apparent enthusiasm to feed the chicks, the provisioners often queue beside the nest, making both themselves and the nest-site conspicuous through their jerky movements and constant chatter. When a potential predator approaches the nest, all group-members join in trying to distract it, by quivering or waving their wings as they hop about.

From the 17th day after hatching, chicks may climb out of the nest and hop along adjacent branches before returning to the nest. At two nests each containing three chicks, two of the young left on the 18th day but the third remained in the nest for a further 24–48 hours, suggesting asynchronous hatching. On their first night out

of the nest, the fledglings sometimes roost separately from their carers, but otherwise they join the group roosting huddle (see General Habits). For the first one or two days they remain close to the nest tree, spending long periods stationary within the canopy, but by the third day they are actively climbing over branches, and flying with the rest of the group, as far as 300 m from the nest.

Parental care by the Varied Sittella is prolonged. Juveniles are fed for at least 60 days, and occasionally up to 80 days, after fledging. This unusually protracted period of care may reflect the time required for the young to perfect the techniques of locating, capturing and dealing with prey. cursory observations indicate that the adults mainly provision juveniles of the same sex as their own, providing a possible mechanism for the young to learn their sex-specific foraging niche. On the other hand, such brood division could be expected by chance if the sexual differences in foraging behaviour of this species are innate and reinforced by dimorphism in bill length.

Breeding success of Varied Sittellas was low in north-east New South Wales, where only ten of 49 nests produced fledglings. Although up to twelve of these nests may have been abandoned before laying commenced, at least six were preyed on. Several groups made four unsuccessful nesting attempts in a single season. For 91 nests recorded in the Birds Australia Nest Record Scheme, success was much higher, at about 62%, but such reports, scattered over the continent, are probably biased in favour of nests that survive the critical early stages.

While the majority of small songbirds in Australia, and even those building well-protected domed nests, are subject to brood parasitism by one or more species of cuckoo, there are comparatively few records of Varied Sittellas being parasitized. Nevertheless, five species of cuckoo have been reported as laying occasionally in the nests of this species; these are the Brush (*Cacomantis variolosus*), Fan-tailed (*Cacomantis flabelliformis*) and Pallid Cuckoos (*Cuculus pallidus*) and Horsfield's (*Chrysococcyx basalis*) and Shining Bronze-cuckoos (*Chrysococcyx lucidus*). It is possible that the apparently low rate of brood parasitism is the result of negative selection pressure, owing to high

To make the most of its superbly-camouflaged nest and to reduce the risks of its lengthy nestling period, the *Varied Sittella* must take care with nest hygiene and concealment. As a result, parents and helpers assiduously remove the nestlings droppings in the form of faecal sacs, and deposit them well clear of the nest-site, so as to avoid drawing potential predators towards the nest. This dramatic photograph also shows to good effect the striking wingbar, formed by a chestnut band on the primaries and secondaries. Its colour and extent vary between subspecies.

rates of nest abandonment or failure in at least some sittella populations.

Few data on longevity are available. At one locality near Sydney, 19 Varied Sittellas were ringed over a period of 20 years, and five were recaptured, all of these within 19 months of initial capture. At another locality, one male was recaptured almost seven years after it had been ringed at the same site.

As intimated earlier, the breeding habits of sittellas in New Guinea are not known. Indeed, virtually nothing has yet been discovered about the behaviour and general ecology of the Black Sittella, a species restricted to the island's mountains.

### Movements

Because they fly at a high level, sittellas are rarely caught in mist-nets. Consequently, there are insufficient data to estimate survival rates or dispersal distances. Up to the year 2001, only 506 Varied Sittellas had been ringed in Australia and New Guinea, and only 32 of these, a mere 6%, had been recaptured, all close to the site of ringing. One was caught at the site at which it had been ringed almost seven years earlier. Observations of colour-ringed individuals in north-east New South Wales suggest that males stay within their natal territory, but that at least some females disperse in their first year, prior to the next breeding season.

### Relationship with Man

No relevant information.

### Status and Conservation

Neither member of the family is considered to be globally threatened. The Varied Sittella has a large range, and its global popula-

tion, although not quantified, is believed to be fairly substantial. This species is common in at least parts of its range, both in Australia and in New Guinea. The Black Sittella is poorly known but seems generally uncommon to rather rare, although it is locally common on Mount Tafa, in south-east New Guinea. Its global population has not been quantified, but it is believed not to be sufficiently low to give cause for concern.

In the period between the two Australian national bird atlases, surveys for the first of which took place during 1977–1981 and that for the second in 1998–2002, reporting rates for the Varied Sittella decreased in some regions but increased in others, and there was no significant change in overall status. As may be expected, the Varied Sittella has declined in many parts of its Australian range where habitat clearance has taken place. In the fragmented landscape of the Australian Capital Territory, in the south-east of the country, the presence of the species was found to be related to the size of woodland remnants and the complexity of the habitat. This species occurs at estimated densities varying from 0.1 to 0.6 individuals per hectare.

There seems to be little threat to either the Varied Sittella or the Black Sittella in New Guinea. Here, both species are confined to mountains, which are generally inaccessible to loggers.

## PLATE 50

## Family NEOSITTIDAE (SITTELLAS) SPECIES ACCOUNTS

### Genus *DAPHOENOSITTA* De Vis, 1897

#### 1. Varied Sittella

##### *Daphoenositta chrysoptera*

**French:** Néositte variée **German:** Spiegelkleiber **Spanish:** Neosita Variable  
**Other common names:** Black-capped Sittella (*pileata*); Orange-winged Sittella (*chrysoptera*); Striated Sittella (*striata*); White-headed Sittella (*leucocephala*); White-winged Sittella (*leucoptera*); Papuan/Mountain Sittella (New Guinea races); Pied Sittella ("albata")

**Taxonomy.** *Sitta chrysoptera* Latham, 1801, Sydney, New South Wales, Australia.

Formerly placed in a separate genus, *Neositta*. Australian races in past treated as five separate species, but each hybridizes and backcrosses with adjacent races; New Guinea races have been treated together as representing a further, distinct species (*D. papuensis*). Described form *albata*, known only from 19th-century specimens from NE Australia (E Queensland), considered an intergrade; other proposed races from Queensland include *rothschildi* (NE area, S to Cairns) and *magnirostris* (Inkerman area), both synonymized with nominate, as also is *lathamii* (from E Victoria); *lumholtzi* (Rockhampton area of E Queensland) is treated as a synonym of *leucocephala*. Eleven subspecies recognized.

##### **Subspecies and Distribution.**

- D. c. papuensis* (Schlegel, 1871) – mountains of Vogelkop Peninsula, in W New Guinea.
- D. c. alba* (Rand, 1940) – Foya Mts, N of R Idenburg, in N New Guinea.
- D. c. intermedia* (Junge, 1952) – W end of Snow Mts (Wissel Lakes area), in WC New Guinea.
- D. c. toxopeusi* (Rand, 1940) – Snow Mts, in WC New Guinea.
- D. c. wahgiensis* (Gyldenstolpe, 1955) – Central Highlands (Mt Hagen–Wahgi Valley), in EC New Guinea.
- D. c. albifrons* (E. P. Ramsay, 1883) – mountains of SE New Guinea.
- D. c. leucoptera* (Gould, 1840) – CN Australia from NE Western Australia (Kimberley region) E to SE head of Gulf of Carpentaria, S to Great Sandy Desert (in W) and about Tropic of Capricorn (in E).
- D. c. pileata* (Gould, 1838) – C & S Western Australia (N to S Great Sandy Desert) E through S Northern Territory and South Australia to far SW Queensland, W New South Wales and NW Victoria.
- D. c. striata* (Gould, 1869) – NE Australia from Cape York S to R Burdekin, in NC Queensland.
- D. c. leucocephala* (Gould, 1838) – CE Australia from R Burdekin S to Queensland–New South Wales border, and inland to Great Dividing Range.

*D. c. chrysoptera* (Latham, 1801) – SE Australia from SC Queensland S through E New South Wales and E Victoria.

**Descriptive notes.** 10–14 cm, mostly 10.5–11.5 cm; 8–20 g (Australian races 10–17 g). Short-tailed passerine with highly variable plumage. Male nominate race has forehead and short diffuse supercilium pale grey, crown to nape, lores and ear-coverts grey-brown (sometimes lores and ear-coverts darker, forming mask), hindneck and neck side greyer with darker shaft streaks; upperparts grey or grey-brown, streaked with dark brown or dusky, uppertail-coverts white to light buffish; tail black with prominent white tip; upperwing black, prominent broad orange-rufous band across primaries and secondaries (mostly concealed when wing folded); chin, throat and malar region whitish to light grey, malar area often with some indistinct dark mottling; underparts white, breast side streaked finely dark brown, undertail-coverts whitish with broken black bars; iris and prominent eyering orange-yellow; bill slightly upcurved, brownish-black with yellowish or orange-brown base; legs orange-yellow. Female is very like male, and sometimes indistinguishable, but often has darker face mask, usually heavier markings on throat and malar region. Juvenile differs from adults in having upperparts brown, boldly streaked white, underparts plain white, eyebrow and ear-coverts white, dark eyestripe (indistinct on lores), orange-buff tips of greater and median secondary wing-coverts, narrow orange-buff tips of greater primary coverts and remiges; iris dark brown, eyering grey, bill black with cream or pinkish swollen gape-flange, legs flesh-brown or grey. Races differ slightly in size, more so in colour of head and wingband, amount of dark streaking on body, and degree of sexual dimorphism in head plumage, in New Guinea also in colours of upperparts and underparts and lack of wingband: in Australia, *striata* is smaller than nominate, with bill straighter and yellow with black tip, cap black, mask dusky-streaked, upperparts with streaking coarser, wingband white and restricted to primaries, underparts more boldly streaked, female has whole of head and neck black; *leucoptera* is similar in size to nominate, has cap black, lower forehead and eyebrow white, otherwise as previous but wingband slightly larger, underparts unstreaked, female with cap more extensive than male's, reaching below eye and onto chin, and lacking white eyebrow; *pileata* is largest race, plumage similar to previous, but upperparts slightly browner and with little or no dark streaking, wingband rufous and extending to secondaries (as nominate), bill slightly upcurved and black-

ish with basal third yellowish, female with larger black cap; *leucocephala* is distinctive, head, neck and throat all white (sometimes pale greyish or with narrow grey streaks), well demarcated from streaked breast, rest of plumage much as nominate but streaking above and below somewhat broader and more diffuse, sexes alike; *alba* also has head all white, but upperparts fawn to dark brown, heavily streaked black, wingband concealed on folded wing, underparts tinged buff or smoky brown and streaked dusky; *papuensis* has black cap with black and white streaking below it, female has head and neck grey with dark streaks; *intermedia* male is intermediate between previous two races; *albifrons* has head entirely streaked black and white, underparts heavily streaked, female head all whitish; *toxopeusi* is similar to last but with less black on cap; *wahgiensis* intermediate between previous two races; females of New Guinea races have head and neck white or grey, with or without dark streaks. **VOICE.** While foraging, a single "chip" repeated monotonously, sometimes accelerating to chatter; prior to flight, drawn-out double "see-wee", each note with rising inflexion; soft wheezing note during appeasement or prior to copulation; incubating female, also fledglings and juveniles, give incessant shrill chatter or twitter when food-begging.

**Habitat.** In Australia, occurs in wide variety of dry eucalypt (*Eucalyptus*) forests and woodlands, with shrubby understorey or grassy ground cover, or both; also in tall shrublands dominated by acacias (*Acacia*) such as mulga or western myall (*Acacia papyrocarpa*) in arid regions, as well as woodlands dominated by casuarinas, such as desert oak (*Casuarina decasneana*) or belah (*C. pauper*), or paperbarks (*Melaleuca*). Scarce in wet eucalypt forest (typically with ferny understorey), and avoids rainforests of all kinds. In stark contrast, New Guinea races are confined to montane rainforest and edges at 1400–2200 m, occasionally down to 1075 m and up to 2600 m.

**Food and Feeding.** Insects and other arthropods. Of 992 items in 59 stomachs from NE New South Wales, over a third (36%) were small adult beetles (Coleoptera), mainly of families Curculionidae, Chrysomelidae, Coccinellidae and Elateridae; bugs (Hemiptera) and spiders (Araneae) comprised roughly another quarter (14% and 13% of items, respectively); larvae of beetles (including families Cleridae and Melyridae) and moths (Lepidoptera, including Geometridae) comprised 17% of all items in stomachs, but c. 33% of total biomass; only a third of stomachs sampled contained ants (Formicidae), which represented only 7% of all items. Of 70 prey items recorded during direct observations, 87% were larvae, mostly lepidopteran caterpillars. Other taxa recorded in stomachs from elsewhere include grasshoppers (Orthoptera, including Gryllacrididae), craneflies (Tipulidae), cockroaches (Blattodea), wasps and bees (Hymenoptera), termites (Isoptera), lacewings (Neuroptera) and pseudoscorpions (Pseudoscorpiones). Of 43 foraging observations in mulga in C Australia, 16% involved caterpillars taken from foliage. In SW Western Australia, faeces from four birds comprised mostly beetles (81%) and ants (12%). Forages at all levels, mainly in canopy; e.g. in eucalypt forests in NE New South Wales c. 70% of observed foraging was at heights of 6–15 m and in SE New South Wales 86% at 6–14 m; but in low *Banksia* woodland in SW Western Australia 96% at 2–6 m, and in mulga in C Australia mean foraging height 2.4 m. Climbs rapidly along upperside of branches, usually in zigzag fashion (leaning and peering down one side and then other), away from and towards trunk, as well as up and down tree trunks. In E Australia, forages mainly on bark of rough-barked eucalypts, particularly stringybarks, which were exploited 80% of time in NE New South Wales and in 89% of observations in SE New South Wales; in Western Australia 84% of observations on smooth-barked wandoo (*Eucalyptus wandoo*), and in C Australia entirely on *Acacia aneura*; in monsoon tropics, observed in woodland dominated by partly rough-barked Darwin woollybutt (*Eucalyptus miniata*) or entirely smooth-barked salmon gum (*Eucalyptus tintinnans*), as well as paperbarks. Substrates used differ with type of eucalypt; on stringybarks in E Australia forages mainly on rough bark of trunks and branches (47–97% at four study sites), whereas on smooth-barked gums and boxes dead branches preferred (42–80%). Sexes differ significantly in foraging substrates and heights in NE New South Wales and in Northern Territory (Darwin region), and possibly over entire Australian range; males spend more time than females at lower levels and on rough-barked trunks and boughs, whereas females concentrate on smooth-barked upper branches and twigs. At one site in NE New South Wales where group colour-ringed, juvenile females foraged significantly lower than did adult females, but juvenile males did not differ from adult males, suggesting that intrasexual competition stronger in females or that intrasexual competition reduced while juveniles are dependent. Main techniques are gleaming or scaling bark surface (53–99% in nine studies) and probing in crevices or curled strips of peeling bark (12–47%), with occasional sallies for aerial insects or web-spinning spiders (3–4%); during scaling, exposes prey by wedging lower mandible under flake of loose bark, then dislodging flake by pushing head forwards and upwards, using tip of bill as a pivot. Regularly uses feet (usually left foot) to hold prey on to branch while preparing it for ingestion, or to secure curled strips of bark while probing them. Before ingestion, large caterpillars held in bill, whipped across branch, then pinned down by foot and the viscera extracted and discarded by bill; elytra and head of beetles torn off. Tool use reported once: three individuals using small twig to probe repeatedly in holes made by wood-boring larvae.

**Breeding.** Season (successful) throughout range Jul–Apr, peak usually Aug/Sept–Dec/Jan; often second clutch laid after successful fledging of first brood. Breeds as pair or, more typically, as co-operative group consisting of primary pair and up to seven (usually 2–4) helpers, including juveniles from previous broods as young as 2 months. Socially monogamous, but mate-guarding suggests potential for extra-pair copulations; several instances of two females laying in one nest; large, weakly defended territory (13–20 ha) or home range. Nest built by primary pair and any helpers present, taking 3–9 days to complete structure, although lining may be added for further 10 days; a neat, deep cup c. 7–8 cm deep externally, tapering at bottom (external diameter c. 5 cm at top, 2.5 cm at base), composed of bark and spider egg sacs, occasionally with addition of fur, plant down or lichen, decorated on outside with flakes or strings of bark, and bound together with spider web. Lined with spider egg sacs, soft bark, moss or lichen, and sometimes wool, fur or feathers; placed in upright fork (colour and texture of nest closely matching those of supporting branch) typically in dead branches of eucalypt (of 57 nests at site in NE New South Wales, 88% in stringybarks, 95% in dead branches), sometimes in casuarina (*Casuarina*), acacia or paperbark, usually in top half of tree at height of 2.5–40 m (average of 230 nests 9.3 m), at two localities in NE New South Wales respective averages 11.3 m and 13.1 m; sometimes builds nest in same tree, even same fork, over several successive seasons, occasionally within same season (for second brood). Clutch 1–5 eggs, mode 3, mean of 39 clutches 2.6, laid on alternate days, probably at intervals of c. 48 hours; incubation (from second egg in some 3-egg clutches, third egg then hatching asynchronously) by primary female (at one nest with two clutches, the two females incubated alongside each other), fed on or near nest by primary male and any helpers present, incubation period 19–20 days; chicks brooded by primary female for 9–14 days, diurnal attentiveness decreasing from 60% of time at

first to 35% by day 8 at one nest, nocturnal attendance ceasing after 15–16 days; primary male and helpers feed young directly or pass food to brooding female, latter then passing it to young or sometimes (24% in one study) eating it herself, mean of 12–20 feeds per hour but reputedly 44 feeds in one hour of observation; nestling period 18–20 days, but if hatching asynchronous youngest chick may leave nest 48 hours after others; juveniles largely independent by c. 2 months, but occasionally fed for up to 80 days after fledging. At two sites in NE New South Wales, respectively 12.5% of 24 nests and 28% of 25 nests produced fledglings; success of 91 nests at other sites combined was higher, at 61.5%.

**Movements.** Resident; all recoveries of ringed individuals were less than 10 km from site where ringed.

**Status and Conservation.** Not globally threatened. Locally common, in both Australia and New Guinea. Estimated densities in Australia 0.1–0.6 birds/ha. Although reporting rates decreased in some bioregions between the two Australian national bird atlases (1977–1981 and 1998–2002), they increased in others, and there was no significant change in overall status. Has declined in many parts of range where habitat clearance has taken place. Within 72 woodland remnants ranging in size from 1.1 ha to 1617 ha, in the fragmented landscape of N Australian Capital Territory, this species' presence was significantly affected by remnant size and habitat complexity. Not at any apparent risk in New Guinea, where confined to relatively inaccessible areas in mountains.

## 2. Black Sittella

### *Daphoenositta miranda*

**French:** Néosite noire **German:** Prachtkleiber **Spanish:** Neosita Negra  
**Other common names:** Pink-faced Sittella/Nuthatch, Wonder/Mountain Tree-runner

**Taxonomy.** *Daphoenositta miranda* De Vis, 1897, Mount Scratchley, south-east New Guinea.

Three subspecies recognized.

**Subspecies and Distribution.**

*D. m. frontalis* van Oort, 1910 – Snow Mts, in WC New Guinea.

*D. m. kuboriensis* Mayr & Gilliard, 1952 – Central Highlands (Kuhor Range and Mt Giluwe), in EC New Guinea.

*D. m. miranda* De Vis, 1897 – mountains of SE New Guinea (Mt Tafa, Mt Scratchley and Mt Albert Edward).

**Descriptive notes.** 12 cm; 12–17.8 g. Male nominate race has forehead, lores and chin bright pink to red; rest of head blackish, body and underwing generally greyish-black with greyish feather edges (giving obscurely scaled pattern), uppertail-coverts slightly vinaceous; tail blackish, all feathers except central two pairs tipped pinkish-white, this colour broadening to terminal half on outermost feathers; underwing with white inner webs near middle of inner primaries and secondaries (apparent in flight as broad white central bar or flash on flight-feathers), and small white patch on greater under primary coverts; iris dark brown;

bill black; legs dark olive-brown. Female differs from male only in bare-part colours, having iris and legs yellow, not dark brown. Juvenile is duller and greyer than adult, with forehead, chin and upper throat cinnamon or rusty brown, cinnamon-brown tips of body feathers, wing-coverts and tertiaries, male iris greyish-brown, female iris pale yellow. Races differ mainly in extent of pink on head: *kuboriensis* has pink more extensive than nominate, reaching to upper throat; *frontalis* has pink extending to lower throat. **VOICE.** During foraging, several group-members continually utter contact call, described as short, faint, sweet, sucked-in, slightly squeaky "sweek, sweek, sweek", louder in flight than when perched; also utters faint chatter during interactions.

**Habitat.** Upper montane (moss) forest, including partly cleared areas; mainly at 2450–3700 m, descending to 2000 m in SE.

**Food and Feeding.** Largely insectivorous; food includes larvae (to at least 3 cm in length), and spiders (Araneae). Forages mainly on high outer branches (live and dead) in canopy, sometimes on lower branches and trunks; in forest gaps may descend to fallen logs. Hops rapidly along upperside of branches, often in zigzag fashion (leaning and peering down one side, then the other); occasionally clings to underside of horizontal branches, and moves up and around trunks. One observed while digging and pounding repeatedly in bark; another watched when shaking and eating a 3-cm grub.

**Breeding.** Males of nominate race (from Mt Tafa) had enlarged testes in both May and Aug, females had slightly enlarged ovaries in Aug, and one juvenile female found in late Aug; these records indicate breeding during dry season, rather than (as reportedly typical for birds in region) during wet season starting in Oct. Invariably encountered in groups of 3–10 individuals, in one case comprising adults with enlarged gonads, adults with no gonad enlargement, and juveniles (with incomplete skull ossification), strongly suggesting co-operative breeding. No other information.

**Movements.** No information.

**Status and Conservation.** Not globally threatened. Restricted-range species: present in Central Papuan Mountains IBA. Little information; generally uncommon to rather rare, but locally common on Mt Tafa. Little evident threat, as the species is confined to mountain areas generally inaccessible to loggers and not subject to any other extensive disturbance.

**Bibliography.** Beehler *et al.* (1986), Coates (1990), De Vis (1897), Diamond (1972), Gilliard & LeCroy (1968), Iredale (1956), Mayr & Gilliard (1952), van Oort (1910b), Parker (1982a), Rand (1936b), Rand & Gilliard (1967), Sims (1956).

Class AVES  
Order PASSERIFORMES  
Suborder OSCINES  
**Family CLIMACTERIDAE**  
**(AUSTRALASIAN TREECREEPERS)**

- Small, rather stout passerines with medium-length slightly decurved bill, moderately long tail, and relatively short, robust legs with long toes and claws; plumage mostly brown or grey-brown, some more rufous, with paler underparts variably streaked, females often with some reddish colour on head or breast.
- 14–19 cm.

- Australia and New Guinea.
- Forest and woodland, one species in montane rainforest.
- 2 genera, 7 species, 18 taxa.
- No species threatened; none extinct since 1600.

### Systematics

It is not surprising that, until the 1960s, the Australasian treecreepers (Climacteridae) were considered to be members of the widespread family of Holarctic, northern, treecreepers, Certhiidae. Their habit of climbing tree trunks, often in a spiral fashion, in search of bark-dwelling insects and then flying down to the base of the next tree is, indeed, reminiscent of that family, as also are their general morphology and coloration. As is more often than not the case with Australasian passerines, however, appearances are deceptive, for closer analysis of the anatomy and behaviour of these two families reveal striking differences between them, reflecting a vastly disparate phylogenetic history. Moreover, recent biochemical evidence suggests that Australasian treecreepers are among the most ancient of living oscines. The similarities between the Australasian treecreepers and the Holarctic treecreepers thus represent a potent demonstration of evolutionary convergence, the result of two entirely unrelated lineages adapting to the bark-foraging niche.

While recognition of the Australasian treecreepers as a distinct endemic avian family came as early as the 1960s, an understanding of their relationship to other families was not achieved until much later. E. Mayr likened the wing and tail patterns of climacterids to those of the Australasian warblers known as thornbills (Acanthizidae), admitting that such resemblances were superficial. Other authorities favoured an affinity with the honeyeaters (Meliphagidae), on the basis of similarities in morphology, including strong feet and a brush-tipped tongue, plumage features and egg coloration, as well as the bark-foraging behaviour of some honeyeaters. These authors also shared the view that the Australasian treecreepers were less well adapted to climbing than are their Northern Hemisphere counterparts, concluding that their "relatively clumsy" climbing behaviour had evolved recently. This view was firmly contradicted by the anatomical evidence assembled by R. I. Orenstein, who instead proposed links with the birds-of-paradise (Paradisaeidae), bowerbirds (Ptilonorhynchidae) and New Zealand wattlebirds (Callaeatidae) on the grounds of the shared presence of the *M. iliofemoralis* externus muscle in the leg.

Thus, the relatives of the Climacteridae remained a mystery until the early 1980s, when molecular techniques revolutionized scientific thinking about the interrelationships of Australian song-

birds, and provided the first hints of their antiquity. On the basis of their studies of DNA–DNA hybridization, C. G. Sibley and J. E. Ahlquist suggested that climacterids were related to the lyrebirds (Menuridae), the scrub-birds (Atrichornithidae) and the bowerbirds, and that the divergence between the Australasian treecreepers and the lyrebirds occurred as long ago as about 48–45 million years. This news was astounding, given the lack of any obvious morphological similarity between treecreepers and lyrebirds, and at best a superficial one with the latter's closest living relatives, the scrub-birds. Nevertheless, the putative relationship of climacterids with the lyrebirds was subsequently corroborated by a study of cytochrome *b* gene sequences, and the link with bowerbirds has recently received support. A detailed study of the syrinx of Australasian treecreepers, however, revealed that its musculature is unlike that found in any other oscine family, suggesting a long separation of the group from the main stem of songbird evolution.

In short, the phylogenetic position of Climacteridae currently remains unresolved, although there can be little doubt that the Australasian treecreepers are among the most ancient of oscine lineages.

Despite earlier attempts to divide the Australasian treecreepers into three genera, the 1926 Checklist of the Royal Australasian Ornithologists' Union (RAOU) recognized only one genus, *Climacteris*, containing nine species. Three of these taxa were reduced to subspecies in A. Keast's 1957 review, although the view that the form *melanotus*, the "Black Treecreeper", was separate from the Brown Treecreeper (*Climacteris picumnus*) persisted until specimens intermediate in colour and size were collected, in 1970. Similarly, the far north-east Australian subspecies *minor* of the White-throated Treecreeper (*Cormobates leucophaea*) was treated as a distinct species, the "Little Treecreeper", separate from the more southerly races, in the *Interim List of Australian Songbirds* and the *Atlas of Australian Birds*, both published by the RAOU, in 1975 and 1980, respectively. This matter was settled when, in 1980, an isolated intermediate form was discovered in the region linking the two forms. This discovery forced a reassessment of the taxonomic status of the Papuan Treecreeper (*Cormobates placens*), which had been treated by Keast and other Australian reviewers as a subspecies of the White-throated Treecreeper. The current consensus is that the Papuan Treecreeper is more dissimilar in plumage and calls

Seven species in two genera make up the Climacteridae, or Australasian treecreepers. The larger of the genera, *Climacteris*, contains five species, including the **Brown Treecreeper**. Initially, climacterids were considered members of the superficially similar and widespread northern treecreeper family, *Certhiidae*. However, the two families have some striking morphological differences, and a vastly disparate phylogenetic history, providing a potent demonstration of evolutionary convergence.

[*Climacteris picumnus victoriae*,  
Chiltern, Victoria,  
Australia.

to its Australian counterparts than the Australian forms are to each other, bringing the species count of the family to seven. The subspecies *wellsi* of the Black-tailed Treecreeper (*Climacteris melanurus*), previously treated as a full species, is the other of Keast's three demoted forms.

On the basis of patterns of sexual dimorphism, Keast recognized three "species groups", or superspecies, of treecreepers. These are the "*picumnus* group", comprising the Brown, Rufous (*Climacteris rufus*) and Black-tailed Treecreepers, the "*erythrope* group", consisting of the Red-browed (*Climacteris erythrope*) and White-browed Treecreepers (*Climacteris affinis*), and the "*leucophaea* group", containing the White-throated and Papuan Treecreepers. He noted, however, that the last of these groups was distinctive in its sexual dimorphism, as well as in its juvenile plumage and its egg coloration. Indeed, the difference in egg coloration was so striking as to convince A. G. Campbell, in 1913, that the "*leucophaea* group" warranted generic separation. Even so, it was not until the late 1970s that proper comparisons between the three species groups were possible, following detailed ecological and anatomical studies in the field and the laboratory. These studies revealed that the White-throated Treecreeper was profoundly divergent from members of the other two species groups, culminating in its separation, together with the Papuan Treecreeper, from all other species of *Climacteris*, in the resurrected genus *Cormobates*. This treatment was supported by Sibley and co-workers' analyses of DNA-DNA hybridization, which suggested a divergence time between the two genera of about 24 million years. This divergence led to speculation that *Cormobates* and *Climacteris* might not even be each other's closest living relatives, although there is no evidence as yet to suggest that they have different ancestors.

In appearance, the genus *Cormobates*, comprising the White-throated and Papuan Treecreepers of, respectively, eastern Australia and New Guinea, differs from the other species groups of Australasian treecreepers in having females with a rusty-orange cheek spot, as opposed to reddish-chestnut streaks on the upper breast, and juveniles with white shaft streaks on the scapulars and, in the case of young females, a cinnamon-chestnut rump. The bill of the White-throated Treecreeper is finer than that of *Climacteris* species, and it has a pale base on the lower mandible and a terminal notch on the upper mandible, both lacking in *Climacteris*. Its legs are shorter and its toes longer than those of the latter genus, and the undersurface of the hind toe has unique

scaly ridges. The skull and humerus of *Cormobates* also differ in several respects from those of most *Climacteris* species, and *Cormobates* has nine secondaries, excluding the tertials, whereas *Climacteris* has only six.

The distribution patterns and habitats of these two genera indicate quite disparate evolutionary histories, which are reflected in the myriad differences between them in behaviour and breeding biology. The relictual distribution and upland-rainforest confines of the Papuan Treecreeper and northern races of the White-throated Treecreeper suggest that the genus *Cormobates* evolved in rainforests, and only relatively recently expanded into the woodland habitats typical of *Climacteris* species. In the dark interior of the cloud-enshrouded montane rainforest, concealed inside a tree hole, the eggs of *Cormobates*, white with sparse markings, are possibly less susceptible to predation by visually oriented nest predators than are the profusely spotted eggs of *Climacteris* species within the sunlit broken dead limbs, or "spouts", enclosing their nests. While the nestling periods of the two genera are similar, arguing against differences in food availability, the remarkably protracted incubation period of the White-throated Treecreeper and, presumably, the Papuan Treecreeper, 4-6 days longer than those of *Climacteris* species (see Breeding), and long incubation bouts, probably evolved as a means of reducing activity at the nest. Such reduced activity may have been more important in protecting the incubating female from being preyed on than in protecting the eggs from nest predators.

Possibly for the same reason, White-throated Treecreepers, in contrast to *Climacteris* species, roost on the surface of tree trunks, rather than inside hollow spouts. Such exposed sites offer unrestricted escape routes from nocturnal predators, whereas hollow spouts potentially become tombs. The rich vocabulary and audible territorial displays of White-throated Treecreepers (see General Habits, Voice) also seem highly adaptive in the context of communication within dimly lit rainforest. Not only would antiphonal calls or duets, as often performed by many *Climacteris* species, be wasted in such an environment, but they could also serve to attract diurnal predators. The most profound difference between the two genera, however, lies in their sociality. Like so many other woodland-inhabiting Australian birds, all *Climacteris* treecreepers commonly live in groups which breed co-operatively, a system contingent on tolerance towards offspring and other kin, and culminating in helping behaviour (see Breeding). On the other hand, co-operative breeding is rare among rainforest-dwellers. It

may therefore be no coincidence that the basically antisocial White-throated Treecreeper expels its progeny as soon as possible, precluding the evolution of philopatry and co-operative breeding behaviour.

The relationship between the two species groups within *Climacteris* is less certain. Whether the "*erythroptus* group" and the "*picumnus* group" are sufficiently divergent to merit generic separation, as has been proposed for the former, for which the name *Climacterobates* has been suggested, can probably be resolved only by further molecular studies.

## Morphological Aspects

The Australasian treecreepers are small, rather stout oscines with a slightly downcurved bill of medium length, a moderately long tail, and relatively short, robust legs with long toes and claws. They range in body length from 14 cm to 19 cm, and in weight from 17 g to 44 g. The posterior surface of the tarsus, the planta, is rounded and unilaminate, unlike the keeled, bilaminate condition of most passerines. Dissections of various muscular systems of climacterids have revealed several unique characteristics of the family. The extrinsic muscles of the syrinx are grossly asymmetric, and fibre orientation is unusual in several respects. In the hindlimb, the muscle *M. iliofemoralis externus* is completely separated from *M. iliotrochantericus caudalis*. At the base of the tongue, *M. thyrohyoideus* consists of two completely independent portions separated at their origin by *M. tracheohyoideus*. Finally, the ligaments that extend the hallux, or hind toe, of most passerines are absent in Australasian treecreepers.

The plumage of climacterids is unremarkable. Broadly speaking, they are uniformly brown or reddish-brown to greyish-brown on the upperside and paler below. The underparts are variably streaked or spotted, and the undertail-coverts are barred. A broad pale wingbar is prominent in flight. The females generally have some reddish colour on the head or breast, such markings being absent on males. Juveniles of most species are duller than the adults, but are otherwise similar to them. Relatively little is known about the moult of the Climacteridae. The juveniles appear to have either a complete moult or a partial one, and most do not

acquire full adult plumage until the second year. Adults have a single annual moult, which they undertake immediately after breeding.

All members of the family are moderately sexually dimorphic in plumage (see also Systematics), and this dimorphism appears surprisingly early in life. In at least three of the seven species, sexual dimorphism develops during the latter half of the nestling stage. The bill and gape-flange of juvenile *Climacteris* treecreepers are predominantly cream-coloured, whereas those of adults are entirely black. In young *Cormobates*, the gape-flange is also cream in colour, but the culmen is blackish, with yellow on the cutting edge and on the base of the lower mandible, whereas adults have the culmen black and a whitish patch on the basal half of the lower mandible. The legs and feet of juvenile *Climacteris* are flesh-grey, with paler claws, whereas those of adults are blackish. In *Cormobates*, in contrast, juveniles have dark olive-brown legs, with bright yellow behind the tibia/tarsus joint, on the tips of the claws, and on the undersides of the toes, features that darken with age.

In addition to differences in plumage, male climacterids are generally significantly heavier than females, and have a longer wing, bill and, often, tarsus than do the latter. The exceptions are the two species of the "*erythroptus* group", the Red-browed and White-browed Treecreepers, which are sexually monomorphic in all measurements, or, in some populations, are slightly dimorphic in wing length only. The bill of Australasian treecreepers is slender, and about one-half to three-quarters the length of the head; it is slightly decurved on the upper mandible, and that of the White-throated Treecreeper has a slight notch on the tip of the maxilla. The slit-like nostrils are partly covered by opercula. Unlike the lyrebirds and the scrub-birds, the Australasian treecreepers have no rictal bristles surrounding the mouth. The tongue of climacterids has frequently been described as brush-tipped and bifid, or two-forked, and these features have been used to support the argument of a common ancestry with the predominantly nectar-feeding honeyeaters of the family Meliphagidae (see Systematics). On closer inspection, however, the tip of the treecreeper tongue is in fact fimbriated (fringed) and quadrid (four-forked), although the lateral notches are poorly defined. Moreover, fringe-tipped tongues are common among oscines that rarely, if ever, feed on nectar, such as mockingbirds (Mimidae) and currawongs (*Strepera*), the latter being members of the butcherbird family (Cracticidae). Honeyeaters exhibit both quadrid and bifid tongues. Although treecreepers do occasionally feed on nectar and sap, they are primarily insectivorous, and they have been observed to protrude the tongue while probing under sheets of peeling bark, or into cylinders of shed bark hanging from branches and twigs. It seems more likely, therefore, that the forked and fringed tip of the climacterid tongue is an adaptation for scraping or possibly ensnaring hidden prey, and sweeping it into the mouth.

One diagnostic characteristic of the Australasian treecreepers becomes obvious only when the birds fly, as it is not until the broad wings are opened that the pale buff to rufous wingbar is starkly revealed. A similarly coloured and prominent wingbar is present in the sittellas (Neosittidae), a feature that was even cited as evidence for a phylogenetic affinity between the two families. The panel spans almost the entire length of the wing, from the innermost of the secondaries to the third outermost of the ten primaries, and is formed by a pale band across the middle third or basal half of each feather, contrasting sharply with the blackish colour of the trailing edge of the flight-feathers and wing-coverts that border it. Given the possible risk associated with flaunting a conspicuous patch of plumage during flight, it seems likely that the wingbar evolved for its use in appeasement or mobbing displays. In addition, the twelve tail feathers feature a broad subterminal band of black, distinct on all climacterids except the Black-tailed Treecreeper and the black form *melanotus* of the Brown Treecreeper.

Unlike their namesakes in the Northern Hemisphere, the Certhiidae, as well as the woodpeckers (Picidae), the Australasian treecreepers lack the pointed tail feathers with thickened shafts that assist the former groups in maintaining purchase while climbing vertical surfaces. Instead, as the detailed anatomical

The Australasian treecreepers are small, chunky passerines with medium-length, slightly decurved bills, fairly long tails, and relatively short, robust legs. The long toes and claws, and particularly the long, curved hind claw, are adaptations for climbing, as they provide a grip on vertical surfaces. It is therefore no coincidence that proportionately the longest hind claw in the genus *Climacteris* belongs to the devoutly arboreal Red-browed Treecreeper. This species is closely related to the White-browed Treecreeper (*C. affinis*), but suggestions that this species-pair merits its own genus can probably only be tested by molecular studies.

[*Climacteris erythroptus*, McPherson Range, Queensland, Australia. Photo: Graeme Chapman]

Climacterids lack some of the morphological adaptations of other tree-climbing birds, including the stiffened and pointed tail feathers of woodpeckers (Picidae). Instead, they use their stout legs for support when they climb trees, as shown here. A trio of closely related species, including the **Black-tailed Treecreeper**, form a superspecies in the genus *Climacteris*. These species have broader and better-developed foot pads than their relatives, presumably an adaptation for a semi-terrestrial lifestyle.

[*Climacteris melanurus melanurus*, Kakadu National Park, Northern Territory, Australia.  
Photo: Peter Fuller]

studies of Orenstein revealed, the climacterids have evolved longer legs, an increased span of the foot and an elongate hind toe to support the body during the process of climbing. Indeed, the extensor system of the hind claw is unique among passerines, being devoid of both elastic and inelastic ligaments and independent from the extensors of the front toes. Whereas the typical passerine hallucal extensor system permits the release of all toes simultaneously, that of the Australasian treecreepers elevates the hind claw independently of the action of the front toes, giving it greater rotational freedom, and permitting finer adjustments to be made to accommodate irregularities of the substrate. The lack of ligament also increases the strength of the hind claw and contributes to the ability of Australasian treecreepers to withstand compressions and bending forces.

Possession of a long hind claw assists a bird in gripping the substrate, and it is no coincidence therefore that the hind claws which are longest in relation to wing length are found in the most arboreal members of the family, in particular in the Red-browed Treecreeper, the Papuan Treecreeper, and the northernmost race of the White-throated Treecreeper. This adaptation would enable the two last-mentioned species to cling to the typically smooth, unbroken trunks encountered in their rainforest haunts, but it is equally useful to the Red-browed Treecreeper, which forages preferentially on smooth-barked boughs and branches within eucalypt (*Eucalyptus*) forests. The family also exhibits partial syndactyly of the front toes, in which the basal third to two-thirds of the toes are bound together by a common sheath of skin and connective tissue. Beneath this tissue, the third and fourth toes are united for the entire length of the basal phalanx of the former, and the basal phalanx of the second toe is weakly united to the others. Syndactyly may counteract the tendency for gravitational forces to dislocate the toes from the tarsometatarsus.

As with most climbing oscines, the pads on the sole of the foot of an Australasian treecreeper are reduced in size in order to minimize contact between the foot and the substrate, as a result of greater reliance on the large curved claws for support. The degree of modification of these foot pads, however, varies greatly within the family. The slightly broader and better-developed pads of the *Climacteris picumnus* superspecies, namely the Brown, Rufous and Black-tailed Treecreepers, compared with those of the *Climacteris erythrops* superspecies, the Red-browed and White-browed Treecreepers, reflect the greater amount of time spent on the ground by the former. These pads are least developed in the strictly arboreal White-throated Treecreeper, representing *Cormobates*, in which the sole of the hind toe is also

covered in a series of scaly ridges, presumably to increase traction on the substrate. Such ridges are absent from the hind toe of *Climacteris* and other avian climbing genera, but, remarkably, they are present on the African Spotted Creeper (*Salpornis spilonotus*), a member of the Certhiidae. The White-throated Treecreeper is also shorter-legged, especially in the femur and tibiotarsus, and longer-toed than are other Australasian treecreepers. The possession of short legs is probably an advantage to climbers that do not use the tail for support, as it increases the angle between the legs and the trunk, thereby reducing the risk of slippage.

For a small family, the Australasian treecreepers occupy an impressive diversity of habitats. The arid-adapted **White-browed Treecreeper** lies at one extreme, inhabiting acacia and casuarina woodlands in Australia's inland deserts. With the exception of this species and the closely-related Red-browed Treecreeper (*Climacteris erythrops*), male climacterids are significantly heavier, longer-winged and longer-legged than females. All family members are moderately sexually dimorphic in plumage, the female White-browed Treecreeper differing primarily in the rufous upper border to the supercilium.

[*Climacteris affinis affinis*, Yarrara, Victoria, Australia.  
Photo: Peter Fuller]

This **White-throated Treecreeper** has recently finished bathing in a rocky pool. Like other passerines, particularly those inhabiting dusty, arid areas, this species bathes regularly when water is available. Frequent bathing, and the thorough preening which tends to follow, help birds keep their feathers in excellent condition. Given that *Cormobates treecreepers* are significantly more arboreal than those in the genus *Climacteris*, bathing may be the only time that a *White-throated Treecreeper* descends to the ground.

[*Cormobates leucophaea leucophaea*, Jervis Bay, New South Wales, Australia. Photo: Graeme Chapman]

In several features of its hind-limb anatomy, the White-throated Treecreeper, representing *Cormobates*, is more similar to members of other oscine climbing families and genera, such as *Certhiidae* and the genus *Hypositta* of the vangas (*Vangidae*), than it is to other members of its own family, reflecting its disparate and possibly longer evolutionary history (see Systematics).

## Habitat

With the exception of one species found in the mountains of New Guinea, the *Climacteridae* are confined to the Australian mainland. Their absence from Tasmania, and from all of the large forested islands close to the Australian mainland, suggests an inability to traverse sea barriers as narrow as 13 km. This explanation is consistent with their apparently weak flying capabilities, consisting of gliding or undulating flights (see General Habits). It is, nevertheless, also possible that an impoverished insular bark-dwelling arthropod fauna, or competition from other bark-foraging species, may have contributed to the demise of any treecreepers that made a successful sea crossing. The curious disjunction in the distribution of the mountain-dwelling Papuan Treecreeper, however, seems to defy explanation. The range of this species spans the 1600 km of the central cordillera running from east to west through New Guinea, except for a 400-km gap in the central-east part where suitable habitat abounds and competing species are absent.

For a small family, the Australasian treecreepers occupy an impressive diversity of habitats. At one extreme is the Papuan Treecreeper, a denizen of the perpetually damp, moss-covered montane rainforest and subalpine forest up to 3000 m above sea-level in tropical New Guinea. At the other extreme is the arid-adapted White-browed Treecreeper, which occupies acacia (*Acacia*) and casuarina (*Casuarina*) woodlands scattered throughout the inland deserts of southern Australia. The least habitat-specialized member of the family is the White-throated Treecreeper, which is as much at home in subtropical lowland rainforest and cool temperate forest, dominated by southern beech (*Nothofagus*), as it is in eucalypt forests and woodlands. Unlike other, sympatric climacterids, this species is able to survive also in plantations of the exotic Monterey pine (*Pinus radiata*). This habitat tolerance brings the White-throated Treecreeper into fre-

quent contact with the Brown and Red-browed Treecreepers. Interspecific conflict with the Brown Treecreeper is minimized by the latter's semi-terrestrial habits and preference for open spaces. Despite differences in preferred bark types, however, aggressive interactions between Red-browed and White-throated Treecreepers occur regularly, although such encounters are brief owing to the constant dominance of the former, despite the fact that the two species are almost identical in size.

A remarkable range of bark types among co-occurring eucalypt species provides the basis for the partitioning of resources, not only among co-existing and potentially competing species of treecreeper, but also between their sexes (see Food and Feeding). Red-browed Treecreepers consistently forage to a greater extent than do White-throated Treecreepers in eucalypt species with smooth branches or trunks, such as gums, boxes and peppermints, where they concentrate on patches of peeling or shed bark, while the latter species prefers rough-barked trees such as stringybarks and ironbarks.

Non-random habitat use by the semi-terrestrial, co-operatively breeding Rufous Treecreeper has been demonstrated at three spatial scales in the wheatbelt region of southern Western Australia. At the landscape level, wandoo (*Eucalyptus wandoo*) woodland was utilized at a significantly greater rate than were three other widespread vegetation types. Within these woodlands, territory use was positively related to the density of hollow-bearing logs, the density of potential nest-sites, and tree age. Hollow logs provide protection from predators, especially for vulnerable fledglings. Large, old wandoo trees were preferentially selected for foraging. The quality of territories occupied by Rufous Treecreepers was found to have a significant effect on group productivity in terms of the number of fledglings produced per breeding group per season, as well as on the number of fledglings surviving to independence, the number of juveniles surviving to the next breeding season, and the probability of the primary male, but not the primary female, surviving from one breeding season to the next (see Breeding).

## General Habits

During typical foraging activities, Australasian treecreepers launch themselves from the upper portion of one tree and plane

down to a lower position on the next tree. Over longer distances, they use undulating flights, comprising short bursts of flapping interspersed with long glides. Treecreepers normally progress vertically up tree trunks, rather than spirally, and climb outwards along limbs, sometimes upside-down on the underside of branches. When they are climbing vertically, the axis of the body is oriented parallel to that of the trunk, but the legs are held obliquely and widely separated; the forward one is under tension, while the back one is under compression. During movement, the feet are not lifted simultaneously but, rather, the lower foot is released and brought up to the level of the upper one, which is then moved higher. At irregular intervals the placement of the feet is swapped, with an associated slight shift of the body axis. This process is known as "inching", to distinguish it from the "hitching" technique of the unrelated certhiid treecreepers and from "reverse-hopping" families such as the nuthatches (Sittidae) and sittellas. Whereas hitchers maintain purchase on the substrate by using the tail as a brace, inchers and reverse hoppers have longer legs, an increased span of the foot and an elongate hind toe. Occasionally, Australasian treecreepers hop backwards for short distances, but they never assume the upside-down vertical postures of the sittellas during normal foraging activities. *Climacteris* species spend up to half of their time on the ground, where they hop with the feet held parallel and the legs somewhat spread.

A conspicuous characteristic of the *Climacteris picumnus* superspecies, the Brown, Rufous and Black-tailed Treecreepers, is the incessant "twitching", "flicking" or bobbing of the tail, which appears to involve both spreading and up-and-down movements, performed simultaneously. The frequency of tail-twitching varies from two or more flicks per second, as when the individual has recently been disturbed by an intruder, to just a few each minute, as during preening, indicating that its intensity may be related to the nervousness of the display or to the threat posed by the intruder. The fact that the three members of this superspecies are the most social species in the family suggests that this visual display may have evolved as a means by which an individual can alert other members of its group to the presence of intruders, such as individuals from neighbouring territories. Since the birds often tail-twitch when they are alone, however, it seems possible that the function of the display is to warn the intruder that the displayer has detected it.

Just as the two genera of Australasian treecreepers differ markedly from each other in morphology and egg characteristics, indicating a major evolutionary divergence, so do they differ also in their social organization. Although all members of this family are sedentary, holding permanent all-purpose territories that are defended throughout the year, the number of occupants and their behaviour towards each other vary dramatically between *Cormobates* and *Climacteris*. The well-defined territories of the rather unsocial White-throated Treecreeper, in *Cormobates*, are occupied by pairs or by single unpaired males, the latter representing up to 30% in one study population; and, while paired males forage with, and feed, their mates during the breeding season, outside this period each sex tends to occupy, and even defend, separate parts of the combined territory, which covers an area usually of 2–7 ha. The boundaries of territories often shift, such as when one or both members of a pair disappear or when immigrants establish territories among existing ones. Most territories are acquired by the filling of breeding vacancies that arise when a breeder dies or disperses, yet a surprisingly high percentage of vacancies, about 23%, remained unfilled in one study.

White-throated Treecreepers defend their territories vigorously, using a graded series of signals. Males advertise their occupancy of a territory by giving "Piping Calls" or "Crescendo Calls" (see Voice) while patrolling the boundaries. Threat displays start with the raising of the crown feathers and tail-fanning, but even between pair-members this often quickly escalates into audible "tail-clicking", in which one or both birds repeatedly spread the tail partially for a split second, while climbing adjacent trees, usually at the same height. Moderately intense interactions consist of supplantings or chases, generally involving unmated males or mated partners, the female often being the aggressor. When neighbouring males are fighting over a female,

however, physical violence often erupts, the birds scrambling with the feet and claws in mid-air or while scampering up tree trunks with tail-clicks, and sometimes tumbling to the ground with their legs entwined. When a breeding male is lost, it is rapidly replaced; but, when a female disappears, the male may remain unpaired over one or more breeding seasons, before attracting a new mate. Breeding by White-throated Treecreepers is never a group affair; even when a female pairs with two males, the latter aggressively defend adjacent territories. Neither sex is consistently dominant in such interactions.

In stark contrast, the *Climacteris* treecreepers live in pairs or in groups of 3–8 individuals, the latter consisting of a breeding pair and its male and, rarely, female offspring from previous breeding seasons. These groups breed co-operatively (see Breeding), and all group-members defend the territory.

Among most *Climacteris* species, a social dominance hierarchy is evident, one in which males are invariably dominant over females, regardless of age, and younger individuals are subordinate to older ones of the same sex. During potentially aggressive encounters, dominant individuals puff the breast and/or flatten the throat feathers, displaying the sexually diagnostic markings (see Morphological Aspects), and approach their rival while holding the head and neck stretched forwards. The subordinate bird usually appeases the dominant one by crouching, with the head lowered, and the wings raised over the back and fluttered. In the case of the Brown Treecreeper, an aggressor sometimes dives towards the ground from a high perch, gliding on upstretched wings and twisting its body, presumably to accentuate its attack and intimidate its opponents; this gliding flight has been termed "Butterfly Flight". Fighting occurs mostly during conflicts over breeding positions, and usually entails two males jabbing at each other with the bill, and scrambling to get a grip of each other with the feet. Once the feet are interlocked, the birds tumble to the ground, where they may roll around for several minutes, before the loser flees. Such fights can result in injuries, including sores on the face, infected eyes and severe bruising of the abdomen. Territory wars result from coalitions of male helpers trying to force out the neighbouring breeding male and his male helpers. All male group-members, and also extra-group helpers, de-

The *Climacteris* treecreepers have a limited repertoire of just four to six vocalizations. Duets are produced by some species, such as the Black-tailed Treecreeper. Two or more birds call simultaneously, or antiphonally, each giving a different sequence of excited notes. Interestingly, this species lacks a distinctive vocalization of its two closest relatives, the Brown Treecreeper (*C. picumnus*) and Rufous Treecreeper (*C. rufus*). Both these semi-terrestrial species give a churring call when they detect terrestrial predators. It has been argued that the Black-tailed Treecreeper may have no need of this particular alarm call in its vocal armoury, as it is an almost entirely arboreal species.

[*Climacteris melanurus* melanurus, Kakadu National Park, Northern Territory, Australia.

fend the territory from invading coalitions. In one instance, six brothers on their natal territory succeeded in evicting the breeding male on an adjacent territory after several weeks of fighting, including prolonged chases punctuated by physical skirmishes. The oldest of the invading cohort paired with the resident female, and the ousted males became floaters on several neighbouring territories.

The behaviour of parents towards dispersing offspring seems to hold the key to an understanding of the striking differences in social organization between the family's two genera. While co-operatively-breeding *Climacteris* species display parental tolerance, non-co-operative White-throated Treecreepers chase their offspring whenever they find them, explaining why dispersing juveniles of the latter are very surreptitious when moving through the natal territory. These differences in parental tolerance may, in turn, be related to differences in the tactics that they use in order to avoid predation, particularly at the nest. White-throated Treecreepers make use of concealment, remaining silent and immobile once a predator has been detected, and activity at the nest is reduced through very long incubation bouts and low rates of feeding both the incubating female and young (see Breeding). In contrast, Brown Treecreepers have short incubation bouts, and feeding rates at the nest are generally higher because of the provisioning efforts of helpers. Potential nest predators, such as snakes, monitor lizards (*Varanus*), small carnivorous marsupials known as marsupial mice (*Antechinus*), and also possums (Phalangeridae), are actively mobbed by all group-members, which give distinctive alarm calls and utilize a variety of displays, including spreading of the wings, rocking back and forth, and making low swoops and short butterfly flights. In short, the main reason why juvenile White-throated Treecreepers are not tolerated on their natal territory may be that their activity near the nest will make the latter more conspicuous to nest predators. Brown Treecreepers, on the other hand, welcome their offspring because vigilance and predator-mobbing are more effective if performed by a large group.

Despite their social tolerance, *Climacteris* species sleep alone at night. They usually roost inside hollow tree trunks or in spouts similar to those chosen for their nests, and they are consequently well protected both from the weather and from predators. In contrast, the White-throated Treecreeper, and doubtless also its con-

gener, the Papuan Treecreeper, typically roost on the surface of trunks, exposed to the elements. Free of the nocturnal requirement for hollow limbs, White-throated Treecreepers have been found sleeping in an amazing variety of sites, including the walls of houses and of public toilets, a chimney, and the ceiling of a cave. This species and its congener most likely evolved in mossy rainforests, where tree hollows suitable for roosting may be scarce as a result of the rapid decomposition of dead spouts or the smothering of them by epiphytic plants. Roosting on exposed vertical surfaces, however, also offers the benefit of unrestricted escape routes from predators. Given that nocturnal predators, such as most snakes and carnivorous marsupials, rely on their sense of smell rather than on vision, there seems to be no advantage in roosting inside tree hollows. Hole-roosting by *Climacteris* species may, therefore, have evolved as a means of thermoregulation during the cool to cold nights in inland Australia. Young Brown and Rufous Treecreepers often retreat to large tree holes and hollow stumps to escape predation, but such attacks tend to involve diurnal aerial predators. Roost-sites are often used on consecutive nights, but individuals may use three or more widely spaced sites over the course of a month.

For those species for which relevant information is available, comfort behaviour is as would be expected. Preening is frequent in occurrence, and bathing takes place fairly regularly when water is available. White-throated Treecreepers, when bathing, were reported as repeatedly entering the water until they were thoroughly wetted, this behaviour being accompanied by frequent calling.

### Voice

Australasian treecreepers give their typically staccato contact calls frequently through the day in all months of the year. Each species has distinctive vocalizations, but the calls of the *C. picumnus* superspecies (see Systematics) are similar to one another in quality, if not in pitch and pace. The White-throated Treecreeper has the most impressive repertoire, with some ten distinct calls, several of which are sex-specific. The male uses loud tremulous "Crescendo Calls" or rapid "Trills" in encounters with the female, particularly when feeding her during the courtship and incubation stages. When off the nest during the incubation period, the

During typical foraging activities, Australasian treecreepers climb a tree trunk until they reach its upper part, then swoop down to a lower position on a neighbouring tree where they repeat the process. They climb trunks vertically, rather than spirally, and forage outwards along branches, sometimes hanging upside-down on the underside of limbs. The White-throated Treecreeper usually spends around one minute on each tree, scouring up to a fifth of it. Climbing birds keep the body axis parallel to the trunk but hold the feet obliquely and widely separated.

*Australasian treecreepers primarily eat arthropods such as ants, spiders, bugs, flies and beetles, which they find lurking on or beneath tree bark, or on the ground. They capture most of their prey by gleaning, but will also probe, hammer or pull loose bark, flicking out insects. Like some other bark-foraging birds, there are intersexual differences in the foraging behaviour of the White-throated Treecreeper. Males tend to forage higher up in trees than females, and may also spend a greater proportion of their time foraging on trunks and dead branches. It has been speculated that such differences may result from bark-dwelling arthropods being relatively scarce or patchily distributed in space and/or time.*

female gives muted, insect-like monotonal notes, possibly to assist the male in locating her. As he approaches her with food, her calls increase in pitch and speed until they resemble the begging call of dependent fledglings. Moreover, nestlings emit an explosive chatter of eight or more notes, quite unlike any call given by adults. The information that these diverse vocalizations convey seems particularly adaptive in rainforests, the likely original habitat of this species and the sole habitat of its Papuan congener, as the dense vegetation and often low light conditions reduce opportunities for visible contact.

*Climacteris* species have only four to six vocalizations, and none of these appears to be sex-specific. The simplest vocabulary would seem to belong to the White-browed Treecreeper, the penetrating insect-like calls of which may be related to long-distance communication near ground level in its lightly wooded semi-arid habitats. Members of pairs or groups of Red-browed Treecreepers, on the other hand, while foraging high in tall eucalypt forest, keep in close vocal contact by using short antiphonal calls, in which a descending chatter from one individual is followed immediately by a sharp disyllabic retort from another, with little overlap. Despite these totally dissimilar adult calls, the common ancestry of these two closely related species is reflected in the cricket-like begging calls of their nestlings. In the case of the Brown and Black-tailed Treecreepers and probably the Rufous Treecreeper, however, accelerating calls uttered by one member of the group sometimes induce another member to call simultaneously, thus forming a duet, which lasts as long as three seconds, each bird giving a quite different sequence of notes. As with the White-browed Treecreeper, the begging calls of nestlings of these three species are essentially higher-pitched versions of the adult calls.

A distinctive vocalization of both Brown and Rufous Treecreepers is the dissonant rasping chatter, or "Churring Call", given when these species are disturbed by human intruders or are mobbing potential predators. This alarm call is heard most frequently when the birds are flushed from the ground, although it is occasionally uttered as they climb or perch on trees. The fact that it is absent from the repertoire of the Black-tailed Treecreeper, which rarely forages on the ground, suggests that the call may have evolved in response to the threat imposed by terrestrial predators. Since group-living, duetting and tail-twitching (see General Habits) are practised by all three members of the superspecies, whereas alarm calls are not, it is possible that the Black-tailed Treecreeper lost these calls secondarily, after forsaking the ground as a foraging substrate. Whether the function of the alarm call is to warn, or draw together, other members of the group, or to communicate the caller's alertness to the predator, remains unclear.

## Food and Feeding

Climacterid treecreepers eat a wide variety of arthropods found on or beneath the bark of trees, as well as on the ground. In addition, they occasionally feed on tree sap and at times take nectar from flowers.

The stomachs of collected specimens of all Australian members of the family invariably contain many ants (Formicidae), and often little else, leading to the impression that they are ant specialists. Ants, however, because of their hard exoskeleton, are retained in stomachs for longer than are most other arthropods, resulting in overestimates of their importance in avian diets. Moreover, despite the abundance of ants in conspicuous and predictable locations, climacterids visit hundreds of trees daily and spend over 80%, and up to 96%, of the day in foraging, indicating that they are seeking other, more nutritious prey. In north-east New South Wales, the greatest number of ants was eaten during the colder months of the year, when other surface-dwelling arthropods were scarce, suggesting that ants may provide a reliable staple. Thus, rather than gorge on ants, treecreepers apparently snap up individuals opportunistically while searching for more energetically rewarding prey, such as larvae and spiders (Araneae); ants are relatively indigestible, but they are energetically "cheap" to obtain and are a possible source of sugars, which

they sometimes store in the abdomen. Nevertheless, they are rarely, if ever, fed to young.

Australasian treecreepers capture most of their prey by gleaning it from the bark or ground surface, often while actively climbing or hopping, and pausing for only a second. In addition, they commonly probe loose strips of peeling bark while flicking the quadrifid tongue (see Morphological Aspects) rapidly in and out, possibly to ensnare hidden insects. Although they lack the cranial modifications required to enable them to excavate wood, climacterids often hammer and tug at the fibrous or flaky bark of rough-barked eucalypts for periods of, on average, 10–25 seconds in order to expose hidden prey. Two studies of co-existing White-throated and Red-browed Treecreepers in north-east New South Wales showed that both species usually landed and started foraging on tree trunks or boughs at heights of less than 10 m, and, although they may continue to the top of the tree, the average time spent on each tree was about 50–60 seconds, during which they covered less than 20% of the total tree height. Both species selected trees with a diameter at breast height greater than 35 cm more often, and smaller trees less often, than would be expected by chance. The modal distance flown between successive foraging trees was 3–6 m, although one flight was as far as 84 m. Australasian treecreepers occasionally pursue flying insects in the air, and in north-east Queensland a White-throated Treecreeper was observed as it repeatedly chased prey that had been flushed from vegetation.

As with many bark-foraging birds in the Northern Hemisphere, including many species of woodpecker and the Eurasian Treecreeper (*Certhia familiaris*), the sexes of at least two species of the Climacteridae differ in their foraging behaviour. At sites in both north-east and south-east New South Wales, female Red-browed Treecreepers foraged at levels higher than those exploited by males; in the south-east, they tended to forage on trunks more and on branches or loose bark less than males, whereas the inverse was true in the north-east. Male White-throated Treecreepers foraged higher up than females in both regions, but males in the south-east foraged more on trunks, whereas

*The Brown Treecreeper is among the most terrestrial members of Climacteridae. It spends roughly equal amounts of time foraging on the ground and in trees, except in winter and spring, when terrestrial feeding is more frequent. Its taste for ground-dwelling prey may explain its preference for woodlands with an open grassy understorey and a poorly developed shrub layer, conditions that make it easier to forage terrestrially. Even when searching for food in trees, the Brown Treecreeper displays a marked reluctance to venture above the lower levels.*

[*Climacteris picumnus victoriae*, Brisbane Ranges National Park, Victoria, Australia. Photo: Peter Fuller]

those in the north-east foraged on dead branches more than females, at least while breeding. Thus, while intersexual differences in foraging substrates are typical for these species where they co-exist, the nature of these differences seems to be spatially and temporally inconsistent. It is almost certainly no coincidence that intersexual foraging differences have been found only in the two most arboreal of species, disregarding the Papuan Treecreeper, and have not yet been detected among the partly terrestrial species.

The presence of intersexual foraging differences among climacterids, as well as in two other bark-foraging specialists in Australia, namely the Varied Sittella (*Daphoenositta chrysoptera*) and the Shrike-tit (*Falcunculus frontatus*), suggests that bark-dwelling arthropods are relatively scarce or patchily distributed in space and/or time. Indeed, in a forest bird community of south-east New South Wales, intersexual differences were most pronounced among bark-foragers and least developed in ground-foragers, reflecting the reduced options for the partitioning of resources on a single, horizontal plane. In the wandoo woodland of south-western Australia, the Rufous Treecreeper foraged primarily on trees in the autumn, but doubled its use of the ground in winter, suggesting that, during the winter months, arthropod abundance on the ground declines less than that on bark. In agricultural areas only 35 km away, however, this species foraged less on the ground in all seasons, perhaps because of the high density of exotic weeds.

## Breeding

Typically for Australian passerines, the breeding season of treecreepers is long, at least for those of the genus *Climacteris*. Egg-laying usually starts towards the end of the austral winter, in August or even late July, and continues for three to five months. This allows time for potentially two or three broods to be reared, although most nest attempts represent replacement clutches, following the failure of previous nestings; up to six such attempts have been recorded for the Brown Treecreeper. The propensity for second broods, following successful fledging of offspring from earlier broods in the same season, varies among species, populations and years. White-throated Treecreepers rarely attempt to raise a second brood, whereas in one population of Rufous

Treecreepers 46% of the groups attempted to do so, and of these groups 75% were successful. In semi-arid Victoria, 77% of breeding White-browed Treecreepers had second broods in one year when rainfall, especially during the month preceding laying, was above average, whereas none did so in the previous year, when rainfall was below average and egg-laying started later.

*Cormobates* species never breed co-operatively. A female White-throated Treecreeper sometimes pairs with two males, but the males defend two, adjacent territories. In stark contrast, the *Climacteris* species frequently breed in groups, the latter consisting of a socially monogamous breeding pair and its retained male and, rarely, female offspring from previous breeding seasons. These groups breed co-operatively, the offspring helping their parents in the building and defence of nests, in the feeding of the breeding female and in the care of the young. Among White-browed and Red-browed Treecreepers, one-third to two-thirds of pairs, respectively, have a helper or, rarely, two or three helpers, invariably males. In the case of Brown and Rufous Treecreepers, on the other hand, 38% of pairs of the former and 59% of the latter may have up to six non-breeding helpers, invariably males, which may stay in the natal territory for four or more years. Intensive studies of these two species have, however, revealed a complex and possibly unique territorial and co-operative breeding system. Up to six, but more usually two or three, contiguous territories can form what has been termed a "super-territory", within which many individuals help at several concurrently active nests.

In addition to having resident helpers within the group territory, or intra-group helpers, the majority of groups received assistance also from up to five individuals from other territories, or extra-group helpers. Within such "super-groups", territorial boundaries were almost irrelevant for males, which fed nestlings, fledglings and even incubating females in up to five, but more usually two or three, territories on the same day, sometimes visiting two nests within an interval of 15 minutes. Although the genetic relatedness among individuals within super-groups awaits analyses of their DNA, all males in one long-term study appeared to be closely related, being in most cases father and son, brothers or half-brothers. While males never defended their territories against members of their own super-group, females defended against intrusions by females from other territories within the super-territory. Super-groups may form when non-breeding broth-

There is no evidence that Australasian treecreepers feed on aquatic invertebrates, and this **Brown Treecreeper** is probably visiting a pool to drink. This behaviour is probably common in climacterids, given their habitat and diet. Some of their favourite foods, including ants, nectar and sap, are sources of sugars, which are sometimes stored in the abdomen. The Brown Treecreeper will also glean or probe bark and crevices for arthropods such as spiders and beetles, and occasionally it even makes aerial sallies after wasps and flies.

ers acquire adjacent territories through take-overs or through what has been termed "budding", in which a non-breeding male establishes his own breeding territory on a portion of his natal territory. Budding causes shifts in territory boundaries, as does the disappearance of one or both members of a breeding pair or the pairing of adjacent widowed birds.

Courtship consists primarily of the male, while calling, feeding the female. With an insect in his bill and the feathers of his crown raised, the male White-throated Treecreeper usually approaches the female from below, sometimes lowering and shivering his wings while giving trill calls (see Voice). The female may repeatedly reject the offering, even tossing it away after taking it, after which the male will retrieve the food and eventually eat it. Prior to copulation, the male emits repeated crescendo calls (see Voice) from a horizontal perch, lowering his head and body while partly cocking his tail and shivering his wings. When the female arrives, he may lift his wings and tail until they are nearly vertical and then rock slowly from side to side, or simply chase her, until copulation occurs, this taking place on a vertical or horizontal surface. No such elaborate pre-copulatory display by the male has been recorded for the other members of the family. In the case of Brown and Rufous Treecreepers, after the breeding male has presented his offering to the breeding female, the latter may give an "Appeasement Display", sometimes with soft begging calls and tail-fanning; both then spend up to several minutes in hopping excitedly between logs or branches, heads bobbing up and down as if bowing when facing each other, until the female crouches on a horizontal perch, quivering her wings and elevating her tail, before the male mounts her.

Treecreepers are virtually unique among Australian passerines in being obligate tree-hole-nesters. As the region has no excavating birds, such as woodpeckers, tree hollows are the result of microbial action and termites (Isoptera), and it may take 100 years or more for them to develop in the hard-wooded eucalypts. Not surprisingly, therefore, nest-sites are often used more than once, although rarely in the same season. While, in natural circumstances, nests are invariably built in hollow branches, trunks or knotholes of living or dead trees, climacterids have been known to nest in ventilation pipes, in chimneys, under eaves of buildings, in earthen tunnels and, often, in hollow fence posts and nestboxes. An old kettle, hanging from a fence post, was used for

eight consecutive years by one pair of Brown Treecreepers. Within an individual territory, Rufous Treecreepers preferred tree-hollow nest-sites with a spout angle of more than 50° to the horizontal, and with an entrance diameter of 5–10 cm.

Nest-building for the White-throated Treecreeper is the task exclusively of the female. With the *Climacteris* species, however, males often bring materials such as feathers with which to line the nest, helps sometimes queuing for the opportunity to add to the lining. The construction work takes 1–2 weeks to reach completion, but some birds continue to add lining during the incubation and nestling stages. As eggs are sometimes covered, at least partially, by this behaviour, it is possible that it serves to conceal the nest contents from predators.

The nest itself is a thickly woven cup composed mostly of dried grasses and strips of bark, and lined with fur, wool, feathers, plant down, bark fibres, leaves, moss and/or snakeskin. As hollow spouts may be deep, however, they are often packed with up to 40 cm of bark, grass and kangaroo or horse dung, and sometimes charcoal, on top of which the nest is then built, some 8–60 cm from the entrance. The diameter of the nest entrance typically ranges from 6 cm to 12 cm, but some are as narrow as 3 cm, and others are wide enough to be utilized subsequently by birds as large as rosellas (*Platycercus*), Laughing Kookaburras (*Dacelo novaeguineae*) and Dollarbirds (*Eurystomus orientalis*).

Chemical protection of the nest may be the function of "Bill-sweeping", a peculiar behaviour of Australasian treecreepers displayed during the nest-building, laying, incubation and early nestling stages. An adult takes an object to the nest, and then frenetically wipes it back and forth on the wood or bark just inside, around and up to 2 m above and below the nest-hole, as well as on surrounding trees up to 20 m away. The objects used are varied, and include insects or their wings, snakeskin, fur, wool, and even fragments of plastic bags, and the behaviour usually lasts for about 5–15 minutes, but may continue for up to 30 minutes or until the object has almost disintegrated. This ritual is performed by both sexes of the co-operatively breeding Brown and White-browed Treecreepers but, in the case of the White-throated Treecreeper, by the female only, consistent with her lone role in nest-building. The abrasive action of bill-sweeping may serve to erase or disrupt scent marks made by hole-roosting mammals such as possums, which occasionally cause the birds to abandon

nests. Alternatively, the chemical properties of the object may repel potential nest predators such as arboreal lizards, snakes and ants. Similar behaviour is demonstrated in North America by White-breasted Nuthatches (*Sitta carolinensis*), which sweep the bark surrounding their nest-holes while holding beetles; these insects excrete oily fluids that may repel or erase the scent trails of such hole competitors as squirrels (Sciuridae).

The clutch size, typically small for Australian oscines in general, varies between one and three eggs for most Australasian treecreepers, but the average is slightly less than two for three species, and closer to three for the well-studied White-throated and Brown Treecreepers. The interval between the completion of the nest and the laying of the first egg is 7–15 days. The eggs of the *Climacteris* species are probably laid at 24-hour intervals. As with most of the thornbills and bowerbirds, however, White-throated Treecreepers, representing *Cormobates*, lay on alternate days, at intervals of 30–48 hours. At least some second and third eggs of a clutch are laid in the early to middle part of the afternoon. The two genera differ profoundly in egg coloration, the eggs of the White-throated Treecreeper being white with few dark brown to blackish markings, whereas those of *Climacteris* are suffused with pink and densely marked with reddish-brown and lilac-grey spots. Likewise, there are marked differences between the genera in the duration of the incubation period. Despite having relatively protected nest-sites, *Climacteris* species have an incubation period of 16–18 days, similar to that of many other Australian passerines that have much more vulnerable open cup-nests. The White-throated Treecreeper, however, has an incubation period of 22–23 days, suggesting that its eggs are less susceptible to predation than those of treecreepers in the genus *Climacteris*, or that its surreptitious behaviour and lower visitation rates at the nest compensate for the prolonged exposure of its eggs to nest predators.

Among all members of the family, it is the female alone that incubates, spending 60–75% of the day sitting on the eggs. Although she forages for herself while she is off the nest, she is also fed by her partner and, in the case of *Climacteris* species, by helpers, at the entrance to the nest or, more commonly, away

from the nest. When the female White-throated Treecreeper is off the nest, she utters a distinctive "Incubating Call", apparently to encourage the male to feed her. The male, in contrast to when he is courting her, does not call or display when offering food, and flies off immediately after his partner has accepted it. Female White-throated Treecreepers are fed by their mates 1.4–1.9 times per hour at the nest, but an average of 17 times per hour away from the nest. Female Brown Treecreepers, on the other hand, are fed up to six times per hour at the nest alone, helpers providing up to half of the food.

Hatching is usually synchronous, but in some nests the chicks may hatch at intervals of up to 48 hours. The hatchlings are naked except for long tufts of down on the crown and mantle; the remiges appear on the fifth or sixth day, and the rectrices two days later; the eyes open 9–10 days after hatching, when pinfeathers emerge on the underparts. Adult weight is reached by 13 days, and after 15 days the chicks often exceed the average weight of adults of their respective sex. Both parents, and also, in co-operative groups, helpers, feed the young and remove their faecal sacs, although only the female broods the young, in the case of the White-throated Treecreeper for up to 14 days after they hatch. Males continue to feed the incubating female for a few days, although she may pass this food on to the chicks. Feeding rates at the nest vary with the number of helpers, the age of the nestlings, the prey size, the weather and the time of day, but typical rates are in the range of 10–20 feeds per hour. The nestling periods of most climacterid species, typically 25–28 days, are among the longest of those of all Australian passerines, and almost double that of many slightly smaller members of other families. As reasoned above, the slow development of young treecreepers is presumably facilitated by the protection from predators afforded by nesting in hollows. In at least two species, single parents of either sex are capable of successfully raising broods after their mate disappears during the nestling phase, and possibly even if the partner disappears before the eggs hatch.

Despite the relative safety of nest-holes, however, the breeding success and productivity of Australasian treecreepers are not particularly high, and show surprising geographical variation. In

*Climacterid treecreepers are virtually unique among Australian passerines in that they nest only in holes. Since there are no woodpeckers in Australia, tree hollows only develop with microbial and termite action, which means that it may take a hundred years to create a suitable cavity. Suitable treecreeper nest-sites are thus at a premium, and it is not surprising that they are both staunchly defended and used in successive years. This White-throated Treecreeper has been fortunate enough to find a natural hole, but climacterids will also use artificial cavities such as ventilation pipes, chimneys, hollow fence posts, nestboxes and even, on occasion, an old kettle.*

*Climacteris treecreepers* such as the **Rufous Treecreeper** breed co-operatively. Groups of up to six individuals consist of a breeding pair, its male and (rarely) female offspring from earlier breeding events, and sometimes even non-breeding birds from adjacent territories. These helpers defend the territory, build nests, feed the female and tend the nestlings. A pair's breeding success appears closely correlated to the amount of help they receive. Pairs with helpers produce more fledglings, and the greater the number of those helpers, the higher the breeding success.

[*Climacteris rufus*,

north-east New South Wales, the percentage of White-throated Treecreeper nests producing fledglings was 68%, and the mean annual productivity per breeding pair was 1.3 fledglings, whereas nest success and productivity in central-west New South Wales were less than half of those figures, being 24% and 0.54, respectively. Similarly, for Brown Treecreepers at the same study sites, the mean annual productivity per breeding group in the north-east was 1.36, about twice that at the central-west locality, where only 0.74 fledglings were produced per breeding unit. These apparent differences in reproductive success may be due to higher rates of nest predation in central-west New South Wales, which may, in turn, be due to a lower diversity and/or density of nest predators in the more fragmented landscape of north-east New South Wales. In Western Australia, nest success and mean annual productivity of Rufous Treecreepers were much higher in an unfragmented landscape than in a fragmented one: in the former, 77% of nests were successful and a productivity of 2.2 fledglings per nest was achieved, whereas the corresponding values for the fragmented landscape were 46% and 1.1 fledglings. Further, the breeding success of this species was higher on territories with a greater density of hollow-bearing logs, which are used as shelters in which to hide from predators.

Among both Brown Treecreepers and Rufous Treecreepers, pairs with helpers invariably produce more fledglings than do those without, and reproductive success is correlated with group size. Without helpers, breeding males and females contribute equally to the provisioning of the nestlings, but, as the number of helpers increases, breeders reduce their provisioning contributions. Breeding females assisted by many helpers at their first nests are more likely to re-nest after a successful attempt. In one population of Brown Treecreepers, both the number of extra-group helpers and their feeding rate were negatively correlated with the breeding experience of the breeding male. Thus, inexperienced breeders were assisted by neighbouring relatives, apparently to compensate for their lack of intra-group helpers. Of the extra-group helpers recorded in a population of Rufous Treecreepers, 70% helped in territories that were of a higher quality than their own. Conceivably, groups in better-quality territories produce more offspring to fill nearby vacancies, which act as a reservoir of potential helpers in future years. Alternatively, non-breeding extra-group helpers may use the behaviour of helping as a means of assessing the quality of adjacent territories.

For up to five days after leaving the nest, the young of most *Climacteris* species shelter in hollow logs or large tree hollows, where they are fed by all members of the group. In contrast, newly fledged White-throated Treecreepers, in the genus *Cormobates*, perch and climb, albeit clumsily, in the open. Feeding rates decrease gradually until the young become independent, which, for most species, happens 30–40 days after fledging. Indeed, in the case of the co-operatively breeding Brown and Rufous Treecreepers, first-brood juveniles no more than 45 days after fledging are capable of helping their putative parents with the feeding, and even the removal of faecal sacs, of nestlings of later broods in the same season. This is unlikely to occur with the Red-browed Treecreeper, adults of which are known to feed their young for at least 60 days after the latter have left the nest, possibly because the relatively specialized foraging niche of this species, combined with sexual differences in foraging behaviour (see Food and Feeding), may require a longer period of apprenticeship.

In all species of the Climacteridae hitherto studied, both sexes are capable of breeding in their first year, and nearly all females attempt to breed in their first year. As the majority of male Brown Treecreepers spend at least one year, and some more than four years, as non-breeding helpers on their natal territories, the mean age of first reproduction for males of this species, 2.75 years, is greater than that recorded for male White-throated Treecreepers, which is 1.83 years.

In common with many other Australian passerines, climacterids often enjoy long lives. Long-term ringing programmes have shown that White-throated and Brown Treecreepers are capable of living for at least 16 years and 13 years, respectively. Annual adult survival rates of two widely separated colour-ringed populations of Brown Treecreepers and one population of Rufous Treecreepers were very similar, at 75–78%, while those of two populations of White-throated Treecreepers, one co-existing with Red-browed Treecreepers and the other with Brown Treecreepers, were 73% and 86%, respectively. For Rufous Treecreepers, the survival rate of primary males, but not females, was positively related to group size when territory quality had been taken into account. For three species, survivorship of males, whether adult or juvenile, tended to be slightly higher than that of females. Fledgling survival to independence was 100% for White-throated Treecreepers, much higher than for Brown and Rufous Treecreepers, for which the respective values were 85% and 76%.

As is typical of Australian passerines, the *Climacteris* breeding season is long, lasting 3–5 months. This enables pairs to rear two or three broods; the **Brown Treecreeper** has been recorded making six attempts! This bird has brought a moth to the nest-hole, to feed either the female or an average of three nestlings. With such a protected nest-site, one might expect this species to have a protracted incubation period. In fact, the average duration of *Climacteris* incubation (16–18 days) is as short as Australian passerines with more vulnerable cup-nests.

Lochman Transparencies]

Juvenile survival rates of Brown and Rufous Treecreepers were considerably lower again, at 54% and 46%, respectively, reflecting their need to overwinter in their natal territories. Although the sex ratios of both nestlings and fledglings are not significantly biased, males invariably outnumber females in adult populations, even in those of the non-co-operative White-throated Treecreeper.

## Movements

Although the Australasian treecreepers, in common with the majority of Australian passerines, are sedentary, recent radio-tracking studies have revealed an important difference between the two genera in the dispersal of the juveniles. In the case of the White-throated Treecreeper, which is not a co-operative breeder, all juveniles of both sexes disperse soon after attaining independence, which they do 30–40 days after fledging, but for at least a further month they continue to use the natal territory as a base from which to undertake forays, moving surreptitiously so as to avoid detection from their intolerant parents. Such forays range from less than 100 m to more than 2 km, with an average of about 550 m, and last from ten minutes to several days, but juveniles of this species may eventually disperse up to 6 km in their search for breeding vacancies.

In contrast, the dispersal of juveniles of the co-operatively breeding *Climacteris* species is strongly biased towards females. Virtually all males that survive their first winter delay dispersal for at least one year and, instead, become helpers on the natal territory for up to four years. On the other hand, the majority of females, 75–77% in studied populations of Brown and Rufous Treecreepers, leave the natal territory within their first year, and, although they disperse much shorter distances, on average, than do White-throated Treecreepers, shifts of up to 7 km have been recorded. A small proportion of males inherit the natal territory, while those that find immigrant females may begin breeding in a portion of the natal territory, as with budding (see Breeding).

Breeding dispersal invariably involves moving to an adjacent or nearby territory, one where the breeding pair has divorced or one member has died. Fractal dimension analysis, which describes the degree of tortuosity of movements, revealed that the

dispersal search paths of Brown Treecreepers were more thorough than those of White-throated Treecreepers, a reflection of the tolerance of territory-owners of the former species towards dispersing individuals. Moreover, males of both species searched more tortuously than did females, possibly because males need to be thoroughly familiar with the resources of a territory in order to compete successfully for it and to attract females.

## Relationship with Man

No relevant information.

## Status and Conservation

In just over two centuries of European settlement, approximately 70–95% of various Australian temperate-woodland communities have been replaced by agriculture and pasture, remnant woodlands being used for sheep and cattle grazing. These processes have resulted in declines in the range and abundance of over 40% of the species dependent on these woodlands. While none of the Australasian treecreepers is globally threatened, populations of several *Climacteris* species are exhibiting regional declines as a result of loss and fragmentation of their woodland habitat. Consequently, several states now categorize these birds as locally threatened or vulnerable, precipitating a considerable amount of research on the causes of their declines and, in particular, on the effects of habitat fragmentation.

In north-east and central-west New South Wales, Brown Treecreepers are least abundant in small woodland patches less than 20 hectares in extent and are completely absent from remnants smaller than 9 hectares. Unlike many north-temperate species that are sensitive to habitat fragmentation, however, Brown Treecreepers in fragmented habitat are just as successful at breeding as those in unfragmented habitat, and they do not spend more time foraging. Yet a high proportion of groups, 64%, in the more fragmented habitat lacked a female for most or all of the breeding season, and could not attempt nesting, suggesting that the decline of this species in this region was due to a disruption in the dispersal of females. Indeed, when juvenile females from

unfragmented habitat were experimentally translocated to territories that lacked a female, most of these paired and formed productive groups, indicating that females are unable or reluctant to disperse through a fragmented landscape to fill breeding vacancies. Further work revealed that unconnected remnants were more likely to contain territories lacking females than were connected habitat remnants. Moreover, the survival of females was lower in unconnected remnants than in connected ones. It appears, therefore, that Brown Treecreepers are sensitive to isolation, rather than to the area of habitat, and that management of the species depends on retaining or even re-establishing links between isolated woodland remnants.

On the other side of Australia, in the more arid south-west, Rufous Treecreepers in fragmented wandoo woodlands do not appear to be suffering from a lack of females, as unpaired males are virtually absent. Instead, groups in fragmented landscapes experience lower rates of nest success, annual productivity and juvenile survival than do those in unfragmented habitat. Although no differences have been found between fragmented and unfragmented landscapes in the predation rates of artificial nests in hollows, the provisioning rates and the biomass of prey brought to nestlings were lower in the fragmented landscape, suggesting that reduced food availability was an important factor contributing to lower reproductive success. Low nest success was also related to sheep grazing, which leads to soil compaction and reduced shrub and ground cover, and these conditions, in turn, may reduce the availability of invertebrate food. In all except one of four geographically defined local populations within this landscape, studied over two years of average rainfall, fledgling productivity and recruitment were insufficient to compensate for mortality of breeding females. Calculated growth rates for the combined population in the two years of the study were, respectively, 0.69 and 0.85, well below replacement level, and much lower than the rate of 1.04–1.23 on a large, relatively undisturbed reserve of more than 12,000 hectares located 35 km away.

Without immigration from such large areas of habitat, local populations of Rufous Treecreepers within fragmented landscapes are likely to decline gradually to extinction. It has been argued, therefore, that the long-term survival of Rufous Treecreepers in agricultural regions requires the removal of non-native grazing

mammals from habitat remnants, and the cessation of other disturbances, such as the removal of dead wood. Paradoxically, current conservation efforts to exclude grazing from woodland remnants in eastern Australia appear to be contributing to further decline of the Brown Treecreeper, because, in the absence of fire, ungrazed remnants rapidly develop a dense shrub layer and grassy ground cover, which reduce foraging opportunities. Indeed, this species has disappeared from fenced reserves, and is more abundant in state forests and private woodland remnants than in national parks where grazing has been prohibited for decades. This example illustrates the importance of considering the ecological requirements of all, rather than a few, declining species when formulating habitat management strategies.

Perhaps the climacterid most at risk is the patchily distributed White-browed Treecreeper, which is adapted to arid conditions. In south-eastern Australia, over 90% of the *belah* (*Casuarina pauper*) woodlands favoured by this species in north-west Victoria were selectively cleared in the twentieth century, and only a handful of tracts of more than 500 hectares now remain. In this landscape, White-browed Treecreepers are not found in remnants with less than 18.5 hectares of *belah* woodland, although, above this threshold, their density is not correlated with the size of the remnant. In this case, the degree of isolation of remnants and the existence of corridors linking them do not reliably predict the presence of the species. Nevertheless, the persistence of the White-browed Treecreeper in remnants of 20 hectares or more, entirely surrounded by agricultural land, suggests that it is capable of crossing up to 450 km of cultivated land by using the extensive network of "linear" vegetation along roadsides and fence-lines, as well as scattered smaller remnants. The enlarging of existing woodland remnants, the creation of new habitat and the maintaining of landscape connectivity are priorities for the long-term conservation of this species.

Ironically, the species that appears to be least affected by habitat fragmentation in Australia is the only one with an affinity for rainforests. The White-throated Treecreeper remains common in fragmented landscapes, doubtless facilitated by its unusually broad choice of habitats, which range from upland tropical rainforest and exotic pine plantations to the same grazed woodlands as are occupied by Brown Treecreepers. It seems very likely that the ecological flexibility of the White-throated Treecreeper and its lack of sensitivity to fragmentation relate to its unique social organization (see General Habits). Could intolerance towards its own offspring have predisposed the species to the colonizing of fragmented and even novel habitats? There can be little doubt that both delayed dispersal and delayed breeding by *Climacteris* treecreepers are handicaps for populations occupying fragmented landscapes. The requirements of most of these species for open spaces in which to forage, unimpeded by dense ground cover, as well as for tree hollows in which to roost and take refuge from predators, confer further limitations that are lacking in the case of the White-throated Treecreeper. In a part of the world where the economic desires of farmers still largely dictate the management of lands that are marginally productive, the tolerant co-operative lifestyle typical of many Australian species that evolved in the country's fire-prone but relatively benign climate may yet prove to be their downfall.

This female White-throated Treecreeper—sexed by her rusty cheek spot—has probably just brought food to the well-grown nestling, which can be aged by its pale gape line. Female climacterids play the major role in the breeding process. In most members of the family, females build the nest and incubate alone. In exchange, the male feeds the female, mainly away from the nest. Both parents feed the young, as do the helpers in the case of co-operatively breeding *Climacteris*. After fledging, feeding rates decrease gradually until the young become independent 30–40 days after leaving the nest.

## 1. White-throated Treecreeper

### *Cormobates leucophaea*

French: Échelet leucophaea German: Weißkehl-Baumrutscher Spanish: Corretroncos Gorjiblanco  
Other common names: Little Treecreeper (*minor*)

**Taxonomy.** *Certhia leucophaea* Latham, 1801, Sydney, New South Wales, Australia. Genus previously merged into *Climacteris*, but differs in structure (bill shape, leg length, sole pads, skull, secondaries), egg coloration, plumage (juvenile characteristics, sexual dimorphism) and behaviour; generic separation corroborated by molecular evidence. Genus name originally combined with feminine adjectives, so deemed to be feminine. Forms a superspecies with *C. placens*, and has in the past been treated as conspecific. Race *minor* has in the past been treated as a separate species, but birds intermediate between it and nominate race occur in SE Queensland. Five subspecies recognized.

#### Subspecies and Distribution.

- C. l. minor* (E. P. Ramsay, 1891) – highlands of NE Queensland, in NE Australia.
- C. l. intermedia* (Boles & Longmore, 1984) – highlands of CE Queensland.
- C. l. metastasis* Schodde, 1989 – SE Queensland and NE New South Wales.
- C. l. leucophaea* (Latham, 1801) – coast, highlands and W slopes (upper watersheds of Murray-Darling Basin) of SE Australia, from CE New South Wales S to SE South Australia.
- C. l. griseus* (Mathews, 1912) – Mt Lofty Ranges, in SE South Australia.

**Descriptive notes.** 14–16.5 cm; 17 g (*minor*) to 22 g (nominate). Male nominate race is dark brown above, with thin whitish loreal streak, fine grey scaling on forehead, thin whitish broken eyering; contrasting grey rump and tail, latter with black subterminal band; wing with broad contrasting rufous-buff bar across bases of remiges; throat white, merging into yellowish-white on central lower breast and belly; breast side and flanks grey-brown with bold, black-fringed cream-white streaks, undertail-coverts creamy-white with broken black bars; iris dark brown; bill black to grey-black, usually with pale grey or cream basal half of lower

mandible; legs dark grey to black. Female differs from male in having rusty-orange spot on cheek. Juvenile differs in having blackish-edged dull white shaft streaks on scapulars, often fine grey scaling on upper breast, strong cinnamon-brown wash on undertail-coverts and sometimes abdomen, also yellowish cutting edge and base of lower mandible, cream gape, dark olive-brown legs and feet (with soles and rear of tibiotarsal joint yellow); in addition, young female has rump and uppertail-coverts orange-chestnut. Races vary mainly in plumage and in size: *minor* is smaller and darker than others, with little contrast between back and olive-grey rump and tail, greyish-white of throat merging with olive-grey breastband, creamy-buff belly heavily mottled olive-brown and dark grey; *intermedia* is intermediate in size and coloration between previous and nominate; *metastasis* is slightly smaller than nominate, both sexes like nominate male but breast brownish-grey; *griseus* is largest and paler below than nominate. **VOICE.** Typical territorial call (both sexes) a series of penetrating piping notes, repeated rapidly, then slowing and falling slightly, continuing for up to 5 minutes; notes also given singly for contact. Male also gives repeated series of up to 10 upward-inflected notes with slight crescendo, and rippling mellow trill. Female occasionally gives succession of descending and slowing notes; during incubation period, soft notes (like Morse code). Juvenile has distinctive soft trill.

**Habitat.** Wide variety of wooded habitats, including tropical and subtropical rainforest, cool temperate forest dominated by southern beech (*Nothofagus*), wet and dry sclerophyll forests dominated by eucalypts (*Eucalyptus*, such as stringybarks, boxes, peppermints or ashes, and smooth-barked gums) and with shrubby understorey, also riparian woodlands of river she-oak (*Casuarina*) or river red gum (*Eucalyptus camaldulensis*), and inland woodlands of cypress pine (*Callitris*) and brigalow (*Acacia harpophylla*). Survives in small isolated forest or woodland remnants, and in selectively logged areas, but rare or absent in clear-felled or heavily cattle-grazed areas. Lowlands to lower highlands; race *minor* at 300–1200 m in highlands of NE Queensland.

**Food and Feeding.** Adult and larval insects, mainly ants (Formicidae); also spiders (Araneae); occasionally sap from acacias or eucalypts, and rarely nectar. Of 4446 items in stomachs of specimens from NE New South Wales, ants accounted for 92% (49% of biomass) and beetles (Coleoptera) 3% (32% of biomass), remainder mainly bugs (Hemiptera), flies (Diptera), wasps (Hymenoptera), moths (Lepidoptera) and spiders, with smaller numbers of cockroaches (Blattodea), grasshoppers (Orthoptera), lacewings (Neuroptera), termites (Isoptera) and pseudoscorpions (Pseudoscorpiones); ants included six genera, and beetles ten families. Items identified by direct observations at two sites (respective totals of 47 and 26) included spiders (7–20%), insect larvae (32–65%) and adult beetles (0–32%). Forages on bark of trees and shrubs, as well as logs, but rarely on ground; foraging heights depend on heights of available vegetation, mostly on tree trunks (up to 88% in five studies) and branches, as well as twigs (usually less than 4%); males foraged at higher level than females in two studies (in NE & SE New South Wales). In dry sclerophyll forest, prefers rough-barked eucalypts such as stringybarks (45–72% of observations at three sites in NE New South Wales) and ironbarks (36% where present), spending less time on eucalypts with predominantly smooth bark; at one site, females spent more time in stringybarks and less time on dead branches than males, but no such differences found at other study sites. Foraging technique mostly gleaning (up to 82% of observations), but also probing (up to 18%), and hammering and pulling bark (up to 4%); occasionally sallies for aerial insects and probes in flowers.

**Breeding.** Season Aug/Sept–Dec/Jan; normally single-brooded. Socially monogamous, normally breeding as pair; individual (of either sex) occasionally maintains pair-bonds simultaneously with two of opposite sex. Nest built by female alone, taking 7–15 days, cup-shaped structure composed of bark fibres, grass and moss, lined with finer bark, fur and feathers, placed inside tree hollow,

with entrance through hole in trunk, or crack in side of limb or end of broken limb (often dead one), sometimes in nestbox; of 67 nest-sites over entire range, 40% in trunk or stump, 36% in branch or broken limb (“spout”) and 24% in nestbox, and of 44 nests in NE New South Wales 70% in trunk and 30% in branch; height of 83 nests over whole range 1–25 m (mean 7 m), and of 25 nests in NE New South Wales 4–13 m (mean 5.5 m); in one study six of 20 nests were used in two consecutive seasons, and in another study only four of 73 sites were used twice; territory 2–12 ha, varying with habitat quality, in C New South Wales (22 pairs) 3–7 ha (mean 6 ha), in NE New South Wales means at two sites 3.9 ha and 5.8 ha (nine and five pairs, respectively). Clutch 2–3 eggs, rarely 4 (mean of 20 clutches over entire range 2.45), dull white with a few rounded spots and dots of dark reddish-brown to purplish-black, mainly at larger end; laying starts c. 10–20 days after nest completed, eggs laid on alternate days (probably at intervals of 40–48 hours); incubation from last or penultimate egg, by female only, fed by male both at nest (1.4–1.9 times per hour) and off nest (17 times per hour for one pair); female attentiveness c. 74%; in two studies, mean stints on nest respectively 24 and 27 minutes and mean absences 10 and 12 minutes; duration of incubation period 22–23 days; young brooded by female for at least 14 days, fed by both parents (male often passes food to brooding female), 9–18 feeds per hour, nestling period 24–26 days; juveniles dependent for c. 35 days, remain in natal territory for up to 75 days post-fledging. Can breed in first year. Maximum recorded longevity 16 years; adult annual survival in NE New South Wales 73% (as low as 21% during drought), in CW New South Wales 87% for males and 83% for females; juvenile survival to independence 100%.

**Movements.** Sedentary. In radio-tracking study, juveniles of both sexes made forays ranging from less than 100 m to more than 2 km in search of breeding positions, eventually dispersing up to 6 km (females farther than males). Of 954 recoveries of ringed individuals, all less than 10 km from ringing site.

**Status and Conservation.** Not globally threatened. Common. Population densities in different parts of New South Wales, 0.1–1.13 birds/ha (0.32/ha in detailed study) in NE, 0.9 birds/ha in CE, and 0.6–0.8 birds/ha in SE; in Victoria 0.2–1.12 birds/ha. Less abundant in burnt than in unburnt open eucalypt forest one year after fire. Able to survive in small woodland remnants and in clear-felled forest where some old trees retained; in tropical rainforest, more abundant in selectively logged areas than in regrowth. Occurs in several protected areas, e.g. Eungella National Park (SE Queensland).

## 2. Papuan Treecreeper

### *Cormobates placens*

French: Échelet papou German: Papuabaumrutscher Spanish: Corretroncos Papú  
Other common names: New Guinea Treecreeper

**Taxonomy.** *Climacteris placens* P. L. Slater, 1874, Hatam, Arfak Mountains, New Guinea.

Genus previously merged into *Climacteris*, but differs in structure (bill shape, leg length, sole pads, skull, secondaries), egg coloration, plumage (juvenile characteristics, sexual dimorphism) and behaviour; generic separation corroborated by molecular evidence. Genus name originally combined with feminine adjectives, so deemed to be feminine. Forms a superspecies with *C. leucophaea*, and has in the past been treated as conspecific. There has been no recent taxonomic revision of this species, and distributional limits are uncertain. Four subspecies traditionally recognized.

#### Subspecies and Distribution.

- C. p. placens* (P. L. Slater, 1874) – Vogelkop (Tamrau Mts, Arfak Mts), in NW New Guinea.
- C. p. steini* (Mayr, 1936) – W & C New Guinea from Weyland Mts E east through Hindenburg Range to Tari Gap area.
- C. p. inexpectata* (Rand, 1940) – Snow Mts, in WC New Guinea.
- C. p. meridionalis* (E. J. O. Hartert, 1907) – mountains of SE New Guinea (E from Aseki area, Mt Kaindi and Herzog Mts).

**Descriptive notes.** 14.5 cm; 12–19.5 g. Male nominate race has dark brown crown with ill-defined pale buff streaks; hindneck to rump and tertials dull brownish-olive, uppertail-coverts as mantle or greyer; upwings darker than mantle, with rufous-buff bar across remiges, and with secondaries and inner primaries broadly tipped pale brown; tail olive to grey with blackish subterminal spot, outer feathers dark olive to brownish-black with broad pale grey or buff tips; throat whitish, merging into buffy grey on upper breast, more ochraceous on belly, flanks dark brownish-grey with buff streaking, lower abdomen spotted buff, undertail-coverts barred dark brown to black; iris blood-red to red-brown; bill black to greyish-black, basal half of lower mandible whitish; legs greyish-yellow to olive. Female differs from male in having conspicuous rusty-orange cheek patch, throat light buffy grey, lower abdomen with larger, black-bordered ochraceous-buff streaks. Immature resembles adult; young female differs from adult female in having abdomen heavily mottled with ochraceous buff and black. Races differ mainly in plumage: *steini* is similar to nominate, but more dark greyish-olive above; *inexpectata* resembles previous, but forehead streaks more sharply defined, rump and uppertail-coverts pure grey, tail greyer, underparts paler; *meridionalis* is browner above than last, more strongly ochraceous on belly. **VOICE.** A mellow series of 5–10 flute-like or bell-like notes, slowly ascending in pitch, with final note sustained; a gradually descending trill similar to that of Chestnut-breasted Cuckoo (*Cacomantis castaneiventris*); and a faint nasal triplet, “chu chee chu”.

**Habitat.** Lower to upper montane rainforest, from 1250 m to 2600 m; also subalpine forest at up to 3000 m in Snow Mts (race *inexpectata*).

**Food and Feeding.** Insectivorous, but no details. Forages mostly in middle to upper levels, but sometimes close to the ground. Climbs jerkily up and around tree trunks, then swoops down to lower level, whereupon it immediately starts climbing again. Usually seen singly, but occasionally in pairs and family parties.

**Breeding.** No information.

**Movements.** Presumably sedentary.

**Status and Conservation.** Not globally threatened. Rarely seen, but reckoned probably to be locally common. As logging and slash-and-burn agriculture are concentrated in the lowlands, the species would appear to be secure in its more elevated habitat. Ecology and biology poorly known; research required.

**Bibliography.** Beechler *et al.* (1986), Coates (1990), David & Gosselin (2002b), Diamond (1972), Gilliard & LeCroy (1961a), Hartert *et al.* (1936), Iredale (1956), Mayr & Rand (1937), Rand (1940a), Rand & Gilliard (1967).

## Genus *CLIMACTERIS* Temminck, 1820

### 3. Red-browed Treecreeper

#### *Climacteris erythrops*

**French:** Échelet à sourcils roux

**German:** Rostbrauen-Baumrutscher

**Spanish:** Corretroncos Cejirrojo

**Other common names:** Red-eyebrowed Treecreeper

**Taxonomy.** *Climacteris erythrops* Gould, 1841, Liverpool Ranges, New South Wales, Australia. Genus name originally introduced with no indication of intended gender, so deemed to be masculine by default. Forms a superspecies with *C. affinis*. Birds from mountain forests of SE coast of Victoria described as race *olinda*, but generally considered indistinguishable from populations in rest of range. Monotypic.

**Distribution.** Coastal and highland forests of SE Australia, from SE Queensland S to Victoria (E from slightly W of Melbourne).

**Descriptive notes.** 15–16 cm; 23 g. Male has dark grey head, neck, rump and uppertail-coverts, contrasting with dark brown rest of upperparts; broad eyebrow, lores and area below eye rusty-orange; upperwing blackish-brown, grey tertials and contrasting pale grey-buff bar across base of remiges; uppertail grey, broad black subterminal band on all except central rectrices; throat dull white; upper breast brownish-grey, lower breast and flanks dark brownish-grey with bold black-fringed white stripes, belly cream with dark spots, undertail-coverts buff-white with broken black bars; iris dark brown; bill and legs black. Female differs from male in having eyebrow, lores and area below eye dark reddish-chestnut, and upper breast striped chestnut and dull white. Juvenile has uniform grey head, lacking rufous eye patch of adult, and few or no markings on underparts, also bill mostly cream, legs flesh-grey. Voice. Typical call a rapid slightly descending chatter with buzz-like quality, often immediately answered by sharp disyllabic call in which second note lower in pitch than first; infrequent calls include a harsh low-pitched grating note, used during aggression, and a high-pitched upward-inflected note, quickly repeated up to four times.

**Habitat.** Open forests and woodlands of Great Dividing Range, as well as coastal and inland slopes; sea-level to c. 1500 m. Commonest in wet sclerophyll forest dominated by eucalypts (*Eucalyptus*) and with well-developed shrubby understorey in gulleys of foothills, but common also in dry sclerophyll forest with grassy understorey on ridges. Prefers forests that support smooth-barked eucalypts (such as Sydney blue gum, flooded gum and mountain gum) as dominants or co-dominants with rough-barked eucalypts. Presence in subtropical or temperate rainforests linked to that of emergent eucalypts.

**Food and Feeding.** Adult and larval insects, mainly ants (Formicidae); also spiders (Araneae). Of 4038 items in stomachs of specimens from NE New South Wales, ants accounted for 87% and beetles (Coleoptera) 5%; remainder mainly spiders, bugs (Hemiptera), flies (Diptera), wasps (Hymenoptera) and moths (Lepidoptera), with smaller numbers of cockroaches (Blattodea), grasshoppers (Orthoptera), lacewings (Neuroptera), termites (Isoptera) and pseudoscorpions (Pseudoscorpiones). Of 47 items identified by direct observations at one site, 63% were insect larvae and 20% spiders. Forages mostly on tree trunks, branches and twigs, and occasionally on logs or on ground (1% in two studies), and at all heights; in New South Wales, 21% of foraging time spent below 6 m in NE and 44% of observations below 4 m in SE, and in both regions females spent more time at upper levels than did males. In NE New South Wales, foraged in boxes (with scaly bark on trunk and patches of loose peeling bark on otherwise smooth branches) more often and in stringybarks (with persistent fibrous, often corrugated bark) less often than did co-existing *Cormobates leucophaea*; females stayed longer in each tree (in both boxes and stringybarks) and foraged in rough-barked boxes more often than did males. Foraging on trunks and large boughs 42–58% in NE New South Wales, these substrates used by males more than by females, while females favoured branches and twigs with strips of peeling bark; in SE New South Wales, pattern was reversed. Foraging technique mainly gleaning (62–80%), but also probing (19–31%) beneath sheets of peeling bark on limbs, and inside cylinders of shed bark on twigs; occasionally pulls and hammers bark (4% and 3%, respectively, in SE New South Wales).

**Breeding.** Season late Aug to Jan; sometimes two broods (two of six groups in sole detailed study, in NE New South Wales). Socially monogamous, but no genetic studies of offspring to show extent of extra-pair matings. Breeds as pair, or as co-operative group consisting of one breeder of each sex and one or two helpers, usually male; of 20 breeding unit-years in sole study, 35% were unassisted pairs, and remainder contained one male helper (45%), two male helpers (15%) or one female helper (5%). Nest built mainly by female, male assisting with addition of lining; cup-shaped, composed of bark fibres and dried grass, lined with fur or feathers, placed at bottom of tree hollow, with entrance through hole in trunk, or crack on side of limb or open end of broken limb ("spout"), often dead; of 29 nests at one locality, 83% in spout and 17% in trunk or bough (62% in live tree, 38% in dead tree); 18 nests over entire range 2.5–30 m (mean 14.5 m) above ground, and 27 nests in NE New South Wales 5–20 m (mean 10.6 m) up; of 21 sites in sole detailed study, five used in two or more consecutive seasons; territory stable from year to year, size 8–20 ha. Clutch 2 eggs, lustrous, pale pinkish-white, thickly freckled with purplish-red and violet-grey, especially at thicker end; incubation by breeding female only, fed both at and off nest by breeding male and any helpers present, in one study helpers provided female with 31% of

feedings; incubation period 18 days; chicks fed by both parents, and by helpers if present; in one study, rate of 10 feeds per hour, 32% by breeding female, 42% by breeding male and 26% by helpers; nestling period 25 days; juveniles dependent for at least 60 days after leaving nest, and one record of juvenile fed by adult 80 days after fledging. Of 22 fledglings, 41% dispersed or died within two months of fledging and six (22%) of remainder survived into following winter; mean annual adult survival 79%.

**Movements.** Sedentary.

**Status and Conservation.** Not globally threatened. Moderately common in suitable habitat. Absence from isolated patches of forest in NE New South Wales suggests vulnerability to clearance and habitat fragmentation, although has been recorded in forest patches as small as 12 ha. Absent from pine (*Pinus*) plantations despite presence in adjacent eucalypt forests.

**Bibliography.** Barrett *et al.* (2003), Blakers *et al.* (1984), Friend (1982), Higgins *et al.* (2001), Loyn (1985b), Noske (1979, 1984, 1985c, 1986, 1991b), Pizzey *et al.* (2005), Recher & Holmes (2000), Recher *et al.* (1985), Schodde & Mason (1999), Simpson *et al.* (2004), Smith (1985).

### 4. White-browed Treecreeper

#### *Climacteris affinis*

**French:** Échelet à sourcils blancs

**German:** Weißbrauen-Baumrutscher

**Spanish:** Corretroncos Cejiblanco

**Other common names:** White-eyebrowed Treecreeper

**Taxonomy.** *Climacteris affinis* Blyth, 1863, Broken Hill, New South Wales, Australia.

Genus name originally introduced with no indication of intended gender, so deemed to be masculine by default. Forms a superspecies with *C. erythrops*. Races intergrade in South Australia (Flinders Ranges). Two subspecies recognized.

**Subspecies and Distribution.**

*C. a. superciliosus* North, 1895 – arid S Western Australia E to ranges of C Australia, and E South Australia (W edge of Flinders Ranges).

*C. a. affinis* Blyth, 1863 – SW Queensland, W New South Wales, NW Victoria and SE South Australia.

**Descriptive notes.** 14–16 cm; 21 g. Male nominate race has broad white eyebrow contrasting with black lores, tapering above ear-coverts, which are streaked black and white; crown and hindneck dark grey, grading into brown on mantle and scapulars; rump, uppertail-coverts and uppertail grey, black subterminal tailband; upperwing blackish-brown, grey tertials, broad buff bar across middle of remiges; chin white, grading to pale brownish-grey on throat and upper breast, with lower breast, belly, vent and flanks boldly striped black and white; undertail-coverts white with broken black bars; iris dark brown; bill and legs black. Female differs from male in having eyebrow bordered above by thin reddish-brown line, and centre of upper breast striped reddish-brown and dull white. Juvenile has duller facial pattern, with supercilium and streaking on ear-coverts less distinct, also bill pale grey, with pinkish-grey at base of lower mandible, gape white; young female has rufous markings on supercilium and upper breast less distinct than on adult. Race *superciliosus* differs from nominate in having rump, uppertail-coverts and tail same colour as mantle (not grey). Voice. Main call a ringing insect-like trill, sometimes described as "rasping call"; also a louder whistle, "tinker-tinker-tinker". Calls not well understood, as given infrequently.

**Habitat.** Tall shrublands and low woodlands of arid and semi-arid regions, usually dominated by acacias (*Acacia*), such as mulga, gidgee and western myall, or by belah (*Casuarina pauper*), buloke (*Allocasuarina leucomammii*) or native cypress pine (*Callitris*); less often in mallee or sugarwood (*Myoporum*) shrublands and riverine woodland. Understorey may be open or grassy, e.g. spinifex (*Triodia*), or shrubby (often dominated by species of the Chenopodiaceae).

**Food and Feeding.** No detailed studies. Food mainly ants (Formicidae), but also small numbers of spiders (Araneae), beetles (Coleoptera), moths (Lepidoptera), flies (Diptera), termites (Isoptera), and various insect larvae. Arboreal and terrestrial. Ascends trunks and branches of both living and dead trees, and hops along fallen trees, among logs and litter, and on bare ground, particularly where abundant shrubs; sometimes feeds at ant nests.

**Breeding.** Season Jul (Western Australia) or late Aug (Victoria) to late Nov, but timing differs from one year to another; majority attempt second brood in years with good rainfall. Breeds as pair, or co-operatively in group consisting of one breeder of each sex and up to three helpers, invariably males; in sole detailed study (in NW Victoria), 65% of 26 breeding unit-years involved unassisted pairs, and remaining pairs had one helper (31%) or three helpers (4%). Both parents and helper males brought material to nest, continuing during incubation; nest composed mainly of bark fibres and dried grass, lined with fur, hair, wool, feathers or vegetable down (some nests entirely of fur or wool), placed in tree hollow (depth of 13 hollows 8–42 cm, mean 17.4 cm), often in dead tree or dead limb of live one, with entrance through hole or split in trunk or in open end of broken limb; of 17 nests at one locality, 82% in live (versus dead) tree and 71% in belah, and 85% of 13 nests were in trunk (as opposed to limb); 20 nests over entire range 1.1–5 m (mean 2.3 m) above ground, and 17 nests in NW Victoria 2–5.2 m (mean 3 m) up; territory all-purpose, permanent, 6–6.11.2 ha (mean 8.4 ha), size not correlated with group size. Clutch 1–3 eggs, usually 2 (mean of 38 clutches in NW Victoria 1.95, of 13 in Western Australia 1.85), slightly lustrous, pinkish-white, thickly freckled and spotted with reddish and purplish-brown, especially at thicker end; incubation by breeding female only, fed (usually at nest entrance) by male and helpers, female's attentiveness varied, females in pairs incubated for 45% of time during first 10 days and 58% thereafter, those in groups for 58–59% of time over entire period; incubation period 18 days; chicks brooded by female for at least 7 days after hatching, for average of 53% of time in four pairs, fed by both parents and any helpers, in one study 7.3 feeds per hour; in first week, hourly feeding rate among pairs (4.75 feeds) lower than among groups (6 feeds), but by third and fourth weeks pattern reversed (10.1 and 7.7 feeds, respectively); also during first week, female provided 37% of food when in pairs (1.75 feeds per hour) and 17% of food in groups (1 feed/hour), but by third week provided 47% (4.8 feeds/hour) in pairs and 31% (2.4 feeds/hour) in groups; proportion and rate of feeding by female higher for pairs (43%, 3.2 feeds/hour) than for groups (31%, 2.2 feeds), and for groups helpers provided 26% of food overall (1.8 feeds/hour); nestling period 26 days; dependent for less than 37 days after fledging. Mean annual adult survival of a population in NW Victoria 72–85%, higher for males (75–87%) than for females (69–84%).

**Movements.** Sedentary.

**Status and Conservation.** Not globally threatened. Relatively uncommon. Considered vulnerable in Victoria, where its range has contracted due to selective clearing of its preferred habitats of belah and buloke woodland, which now cover only 10% of their original extent in this region. Not found in belah woodland remnants of under 19 ha, and less common on sites grazed by livestock.

**Bibliography.** Barrett *et al.* (2003), Blakers *et al.* (1984), David & Gosselin (2002b), Higgins *et al.* (2001), Houghton (1998), Macdonald (1969a), McCarthy (2006), McCulloch & Saunders (1999), Noske (1980b), Pizzey *et al.* (2005), Radford (2004), Radford & Bennett (2004, 2006), Schodde (1993), Schodde & Mason (1999), Simpson (1997), Simpson *et al.* (2004).

## 5. Brown Treecreeper

### *Climacteris picumnus*

**French:** Échelet brun **German:** Braunbaumrutscher **Spanish:** Corretroncos Pardo  
**Other common names:** Black/Black-backed Treecreeper (*melanotus*)

**Taxonomy.** *Climacteris picumnus* Temminck, 1824, southern Queensland, Australia.

Genus name originally introduced with no indication of intended gender, so deemed to be masculine by default. Forms a superspecies with *C. rufus* and *C. melanotus*. Races intergrade. Race *melanotus* has been considered a separate species, but specimens intermediate in colour and size between it and nominate occur. Three subspecies recognized.

#### Subspecies and Distribution.

*C. p. melanotus* Gould, 1847 – N Queensland (from Cape York S to R Burdekin), in NE Australia.  
*C. p. picumnus* Temminck, 1824 – C & E Queensland (from lower R Burdekin) S to SE South Australia.

*C. p. victoriana* Mathews, 1912 – E seaboard and Great Dividing Range from SE Queensland (Bunya Mts) S to coastal W Victoria (The Grampians).

**Descriptive notes.** 14–18 cm; 22–44 g. Male nominate race has brownish-grey crown and neck, blackish-grey lores and eyestripe, broad creamy supercilium, indistinct narrow whitish broken eyering, and buff ear-coverts streaked dark grey posteriorly; upperparts, including upwringing-coverts and tail, mid-brown, with broad black subterminal tailband; flight-feathers blackish-brown, broad pale buff diagonal bar across middle; cheek, chin and throat whitish to greyish-cream; breast light brownish-grey with small central patch of black and white streaks, lower breast, belly and flanks buff-brown with finely black-edged white

stripes, undertail-coverts buffy white with broken black bars; iris dark brown; bill and legs greyish-black. Female is like male, but with streaks on breast chestnut and white. Juvenile differs from adult in having head darker and greyer, with indistinct pale grey supercilium, upperparts slightly darker and browner, markings on breast centre smaller (male) or hidden (female), streaking on lower underparts off-white and bordered with black spots (rather than lines), flanks, vent and undertail-coverts washed rufous-brown; bill dark grey with whitish cutting edges and gape, legs flesh-grey. Race *victoriana* is larger than nominate, with head markings duller and less distinct, upperparts browner, cheek, chin and throat often washed rufous, breast with faint pinky wash; *melanotus* is smaller than others, has upperparts uniform blackish-brown, and pale creamy-white bold supercilium, anterior ear-coverts, cheek, chin and throat contrasting with brownish-black crown, eyestripe and posterior ear-coverts. Voice. Main call a slightly upward-inflected staccato “pink”, singly or repeated slowly 5–10 times on descending scale, sometimes accelerating and culminating in melodious whistles or cackles; also a series of 4–100 weaker monotonal notes with slight crescendo; harsh rasping rattle (usually in alarm); less frequently heard food-begging “ding” call, wails and chirps. Both sexes call, sometimes simultaneously, apparently duetting.

**Habitat.** Mostly woodlands dominated by eucalypts (*Eucalyptus*), especially rough-barked species such as stringybarks or boxes, usually with open grassy understorey and poorly developed shrub layer, and often with dead trees, abundant fallen timber or both. Also in open eucalypt (dry sclerophyll) forests comprising ironbarks or boxes or gums; found also in mallee woodland or shrubland, in river red gums (*Eucalyptus camaldulensis*) or river she-oaks (*Casuarina*) along creeks, in cypress pine (*Callitris*), in acacia (*Acacia*) open woodland (e.g. gidgee) and in semi-cleared pastures. Occurs in both unburnt and annually burnt habitats.

**Food and Feeding.** Adult and larval insects, mainly ants (Formicidae); also spiders (Araneae); also occasionally takes nectar and sap from eucalypts. Of 3339 items in stomachs of specimens from NE New South Wales, ants represented c. 75% and larvae c. 20%; remainder mainly beetles (Coleoptera, of at least eight families), spiders, bugs (Hemiptera), flies (Diptera), wasps (Hymenoptera), grasshoppers (Orthoptera) and moths (Lepidoptera). At least nine genera of ants eaten; of 3303 ants from 22 specimens in one region, 63% were of genus *Iridomyrmex* and 6.5% *Crematogaster*. In 51 direct observations of feeding, larvae comprised 80% of prey and beetles 10%, but no ants recorded. Forages in trees and on ground in approximately equal proportions. At two sites in NE New South Wales, foraged on the ground or on logs 37–49% of time, on tree trunks c. 30–40% and on branches c. 10–20%; ground-foraging more frequent in winter and spring. At other sites in same region, 65% of foraging time spent on ground, 8% on logs, stumps and dead trees, and remainder on live trees (74–79% of time on trunk, 16–19% on boughs, and 5–7% on smaller branches). Prefers lower levels of trees, in one study spending 45% of time below 1 m and 25% at 1–2 m. Prefers rough-barked trees, such as stringybarks (at two sites, 34–55% of trees visited) and ironbarks or rough-barked species of box (28–30%), and less partial towards half-smooth boxes (10–16%), smooth-barked gums (5–6%) and dead trees (16%). Usually flies to base of tree, but sometimes climbs directly on to trunk from ground. Main foraging technique gleaning (more than 90%), but also probes bark strips and crevices; occasional aerial sallying, pouncing and flower-probing. No detected differences between sexes in foraging behaviour.

**Breeding.** Season mid-Jul to early Dec; up to six nesting attempts per season, but usually only one brood (rarely two) successfully reared. Breeds as pair, or as co-operative group consisting of primary (breeding) pair and up to six helpers (mostly males) per nest; helpers are mostly offspring from previous breeding seasons (intra-group helpers), but often also include breeding males and females, and non-breeding males, from adjacent territories (extra-group helpers). Nest-building mainly by breeding female, but breeding male and helpers bring lining material, even after clutch complete; nest a thickly woven cup of grass, bark, leaves, and occasionally human refuse such as aluminium foil, sometimes built on top of platform up to 40 cm deep consisting of grass, dung, charcoal and snake scales, nest lined with fur, wool, feathers, thistle-down and/or snakeskin; usually placed in tree hollow, usually eucalypt, with entrance through hole in trunk or crack in side of limb, or open end of broken limb (“spout”), often dead one; of 41 nests at one site in NE New South

Wales, 85% in dead tree or stump, 10% in dead spout of living tree and 5% in hole in living tree (63% were in vertical hollow, rest inclined or horizontal), and eight sites were reused in consecutive or subsequent years; artificial sites (e.g. hollow fence posts, nestboxes, chimneys, ventilation pipes, even old kettle) also used; nest-entrance diameter 6–13 cm, depth of hollow 20–260 cm (mean 59.3 cm); height above ground of 112 nests from different parts of range 0.3–25 m (mean 4 m), and of a further 41 nests in NE New South Wales 1.2–12.2 m (mean 4.9 m); territory permanent, in New South Wales 1.5–4.5 ha (average 3.4 ha) in CW region and 6.8–20 ha (correlated with size of group) in NE, boundaries shifting only after disappearance of one or both members of breeding pair, or when non-breeding male establishes own breeding territory on a portion of his natal territory (known as “budding”); “super-territories” comprise up to six adjacent territories, among which group-members may move and help at several nests. Clutch 2–4 eggs, usually 3 (mean of 37 clutches throughout range 2.65, of 33 in NE New South Wales 2.82), smooth and slightly lustrous, pinkish-white ground almost obscured by freckles and mottling of purplish-red and reddish-brown (sometimes bigger and more numerous at larger end), with a few underlying violet-grey spots; laying interval normally 24 hours, but two instances of third egg laid at least 42 hours after second; incubation by female only, fed on nest by breeding male and by any helpers present, female attentiveness 57–63%, mean duration of incubation bouts in NE & CW New South Wales 12 and 17 minutes, respectively, and breaks 7 and 9 minutes; incubation period 15–16 days; chicks brooded by female (male continues to feed her for few days after young hatch), fed by both parents and by any helpers in group, 14.7 feeding visits per hour (50 nests, CW New South Wales); contribution of helpers often equal to that of primary pair but up to 60% (varies with number in group); nestling period 21–26 days; juveniles dependent for c. 30–40 days after fledging; female capable of laying complete second clutch within 14 days after first brood fledges, and she will feed nestlings of second brood; most males (95%) that survive first winter delay dispersal from natal territory for at least one year, while majority (75%) of such females leave to search for breeding positions. Able to breed in first year. Maximum recorded longevity 13 years 11 months post-ringing; in South Australia, 10% of individuals recovered at least 6 years old; annual adult survival 76–78% in two studies (NE & CW New South Wales) and juvenile survival (to dispersal stage) 50% and 54%, respectively.

**Movements.** Sedentary. Of 752 recoveries of ringed individuals, all were less than 10 km from site of ringing.

**Status and Conservation.** Not globally threatened. Locally common. N populations of race *melanotus* in far N Queensland have declined, and their range contracted since at least 1930s, probably as a result of increased severity of fires; these trends may date back to start of European occupation. Densities in S vary from 0.01–0.27 birds/ha (NE New South Wales) to 0.42 birds/ha (Victoria) and 0.78 birds/ha (CW New South Wales). S populations adversely affected by clearance and fragmentation of habitat, and removal of dead and fallen timber; in NE New South Wales, least abundant in smaller (6–20 ha) woodland patches and absent in smallest ones (less than 6 ha), but a detailed study suggested that connectivity of remnants was more important than remnant size, primarily because of females’ reluctance to disperse over large distances of unsuitable habitat.

## 6. Rufous Treecreeper

### *Climacteris rufus*

**French:** Échelet roux **German:** Rostbauch-Baumrutscher **Spanish:** Corretroncos Rufo  
**Other common names:** Allied Rufous Treecreeper

**Taxonomy.** *Climacteris rufa* Gould, 1841, Swan River, Western Australia.

Genus name originally introduced with no indication of intended gender, so deemed to be masculine by default. Forms a superspecies with *C. picumnus* and *C. melanotus*. E population (in South Australia) formerly considered by some authors to represent a geographical race, *orientalis*, distinct from form in SW Western Australia, but populations in intervening desert said to be intermediate in characters. Monotypic.

**Distribution.** From SW Western Australia (S from about Geraldton) inland through Great Victoria Desert to N Eyre Peninsula, in South Australia.

**Descriptive notes.** 16.5–18 cm; 30–33 g. Male has supercilium, cheek, ear-coverts, chin and throat rich cinnamon-rufous, thin dark grey-brown eyestripe, often grey-brown suffusion on ear-coverts; forehead, crown, hindneck and neck side light brownish-grey, merging into slightly darker olive-brown on mantle, back and upwringing-coverts; rump and upperpart-coverts similar but with rufous suffusion; tail olive-brown, broad blackish subterminal band on all rectrices except central pair; flight-feathers dull black, with broad pale rufous-buff diagonal band across base; underparts cinnamon-rufous, with grey wash across breast,

patch of narrowly black-edged white streaks on centre of upper breast, indistinct thin cream streaking on lower breast, small black spots on undertail-coverts; iris dark brown; bill and legs grey-black. Female is like male, but streaks on upper breast edged with reddish-chestnut (not black). Juvenile (up to 3 months) lacks cinnamon-rufous supercilium, has crown and neck dark slate-grey, throat and upper breast unstreaked (female) or with pale rufous centres (male); bill mostly pale grey or horn-coloured. Voice. Contact call a piercingly high-pitched “tset”, repeated at intervals of 0.5–1 second, or at irregular intervals (then resembling Morse code), interspersed with very rapid trill of notes (c. 20 per second) that quickly ascend and then descend scale slightly; alarm call a harsh chirring. Calls higher-pitched than those of *C. picumnus* and *C. melanotus*.

**Habitat.** Open woodlands and mallee scrub, dominated by eucalypts such as wandoo (*Eucalyptus wandoo*), powderbark (*Eucalyptus accedens*), brown mallet (*Eucalyptus astringens*), salmon gum and various mallees, usually with grassy or shrubby understorey; also abundant in tall sclerophyll forest dominated by jarrah (*Eucalyptus marginata*) and marri (*Corymbia calophylla*) with dense understorey of banksias (*Banksia*), casuarinas (*Casuarina*) or heath. In the wheatbelt of SW Western Australia, wandoo woodland preferred over three other vegetation types (see page 646).

**Food and Feeding.** Mostly ants (Formicidae), but also other insects such as lepidopteran larvae and adults, beetles (Coleoptera), cockroaches (Blattodea), bugs (Hemiptera), wasps and bees (Hymenoptera), termites (Isoptera), dragonflies (Odonata) and grasshoppers (Orthoptera); other inver-

tebrates include earthworms (Oligochaeta), especially when feeding young, also centipedes (Chilopoda), millipedes (Diplopoda) and snails (Gastropoda). Occasionally skinks (Scincidae), and seeds and nectar. Forages at all heights on tree trunks and branches, as well as among litter and logs on the ground. In coastal jarrah forest mostly in trees, ground-foraging accounting for less than 20% of observations. At inland woodland sites, most foraging takes place on ground (65–74%), but seasonal variation: ground used more during winter and early spring, shifting more to trees in late spring through summer and autumn. Females at one site foraged on ground c. 10% more than did males. At one site, when not feeding on ground, foraged largely on wandoo (92% of observations), preferring large trees to saplings. Main technique gleaning (76–78% in two studies); also probes crevices in bark and among litter, and pulls bark from branches; occasionally probes flowers for nectar.

**Breeding.** Season late Aug to early Jan; two broods per season common, three broods recorded once. Breeds co-operatively, with primary (breeding) pair and up to six helpers (mostly males) per nest, also as simple pairs (41% in one study); helpers mostly offspring from previous breeding seasons, but often include also breeding males and non-breeding males and females from adjacent territories. Nest built mostly by breeding female (69% of 146 visits), with some assistance from breeding male and helper males; cup-shaped, built on base of bark strips (up to 30 cm thick) and sometimes dung, then dry grass, cup lined with feathers, fur, wool, plant down and sometimes rabbit or kangaroo dung, placed in hollow branch (“spout”), trunk or stump of living or dead eucalypt, nest-entrance diameter 6–13 cm, depth of hollow 26–91 cm; of 113 nests at one woodland site, 91% in wandoo, of which majority (94%) in spouts (most at angle of more than 50 degrees from horizontal) and 6% in trunks; in jarrah forest, 54% in trunks and 46% in branches; in wandoo woodland, mean height above ground of 48 nests at one site was 8.3 m, and of 12 nests at another site 5.9 m (2.4–13 m); in jarrah forest, mean height of 28 nests was 15 m, but ratio of nest height to tree height was similar in both habitats; of 15 groups that re-nested, five used same site; territory maintained all year, defended by all group-members, defence relaxed in breeding season to allow non-resident visitors, size not related to group size, average at one woodland site 7.8 ha (range 4.6–9.2 ha) but mean of 30 territories at another woodland site 2.6 ha (range 1.6–6 ha). Clutch 1–3 eggs, usually 2 (82% of 34 clutches in one study), slightly glossy, light pinkish-buff, thickly marked all over with dull purple and reddish-brown, laying interval not studied (at one nest, second egg laid 48 hours after first); incubation by female, fed by breeding male and helper males (occasionally) both at nest entrance and off nest, duration of incubation bouts 1–35 minutes (mean 15.8 minutes), incubation period 17 days; chicks brooded by female, young fed by both parents and by any helpers in group (including females), average feeding rate at one site 21.8 visits per hour (range 8–50, dependent on time of day, temperature, and number and age of nestlings); with no helpers, breeding male and female contributed equally; resident helpers (both sexes) contributed similar amount to that of at least one of breeders and, as number of helpers increased, provisioning effort of primary pair declined significantly; nestling period 28 days; juveniles dependent for up to 30 days post-fledging, but first-brood young able to assist in feeding of nestlings and fledglings of second brood; dispersal rates among yearlings higher for females (c. 55%) than for males (23%), about half of surviving males stayed in natal territory for at least 1 year and a further 30% remained for 2 years, whereas 23% and 4% of female fledglings remained for 1 and 2 years, respectively. At one site, 46% of groups re-nested after successful fledging of first brood, and almost 75% of these (mostly groups with helpers) succeeded in raising a second brood. Can breed in first year. Annual adult survival 77% and 75% for breeding males and females, respectively; juvenile survival 76%.

**Movements.** Sedentary.

**Status and Conservation.** Not globally threatened. Locally fairly common to common. Thought to have declined or disappeared in agricultural regions of Western Australia as a result of habitat clearance and fragmentation. Detailed study at site 160 km E of Perth revealed lower reproductive success in fragmented landscapes than in unfragmented ones, this related not to size of habitat remnant but, instead, to higher population densities, and to poorer territory quality caused partly by sheep grazing.

## 7. Black-tailed Treecreeper

### *Climacteris melanurus*

**French:** Échelet à queue noire

**Spanish:** Corretrancos Colinegro

**German:** Schwarzschnanz-Baumrutscher

**Other common names:** Chestnut-bellied Treecreeper; Allied Treecreeper (*wellsi*)

**Taxonomy.** *Climacteris melanura* Gould, 1843, Derby, Western Australia.

Genus name originally introduced with no indication of intended gender, so deemed to be masculine by default. Forms a superspecies with *C. picumnus* and *C. rufus*. Race *wellsi* has in the past been treated as a separate species. Two subspecies recognized.

**Subspecies and Distribution.**

*C. m. melanurus* Gould, 1843 – N Western Australia (E from Broome) and N Northern Territory E to Gulf of Carpentaria uplands and NW Queensland (S to Tropic of Capricorn).

*C. m. wellsi* Ogilvie-Grant, 1909 – Pilbara region of W Western Australia.

**Descriptive notes.** 16–19 cm; 32 g. Male nominate race is blackish-brown above, with indistinct fine white streaks on ear-coverts; upperwing similar, with broad pale cream-buff band across bases of remiges (conspicuous in flight); uppertail blackish-brown; chin, throat and upper breast covered with coarse black-edged white streaking, streaks becoming sparser across lower breast; rest of underparts dusky brown with fine black streaks (except on flanks), undertail-coverts blackish-brown with white lateral spotting; iris dark-brown; bill black; legs dark grey to blackish, pale soles. Female differs from male in having chin and

throat white, bordered with broadly chestnut-edged white streaks on upper breast. Juvenile has chin and throat black-brown with indistinct streaking (male), or dull white with brown mottling (female), rest of underparts much darker, bill and gape-flange pinkish-white. Race *wellsi* is similar to nominate but slightly smaller, and brighter, with neck, side of breast and flanks deep rufous-brown, lower breast and belly pinkish-buff to light cinnamon-brown with indistinct dusky streaks, undertail-coverts broadly and more uniformly barred white. **Voice.** Contact calls strident, high-pitched “ching” or downward-inflected disyllabic “chee-ting”, singly or repeated at intervals of 1–2 seconds. Also, a rapid succession of thinner “peep” notes (8 or more per second). Also sustained “songs” consisting of a series of slightly descending notes, at first accelerating, then slowing, often followed by, or in duet with, shrill, somewhat siren-like, rising and falling “wee-a” notes, repeated six or more times, given by a second individual.

**Habitat.** Open eucalypt forests, woodlands and savannas in monsoon-tropical and semi-arid regions, dominated by such species as Darwin woollybutt (*Eucalyptus miniata*), Darwin stringybark (*Eucalyptus tetradonta*), northern salmon gum (*Eucalyptus tintinnans*) and variable-barked bloodwood (*Corymbia dichromophloia*), often with grassy understorey, but frequently on stony ridges and slopes with little or no understorey; also in riparian woodland with river red gums (*Eucalyptus camaldulensis*), and in acacia (*Acacia*) thickets if eucalypts present.

**Food and Feeding.** Relatively little known. Food mainly ants (Formicidae) and beetles (Coleoptera), also moths (Lepidoptera), grasshoppers (Orthoptera) and unidentified insect larvae, also spiders (Araneae); occasionally visits flowers (e.g. *Xanthostemon paradoxus*), probably for nectar. In one study, foraged on trunks and large branches (75%), dead branches (6%) and foliage (11%) of trees; also on shrubs (3%) and ground (5%). On trees, most foraging at 8–14 m (40%) and 4–7 m (34%) above ground; remainder mostly below 4 m (21%). Foraging techniques primarily gleaning (73%) and probing (21%).

**Breeding.** Comparatively little known. Season Jun–Jan; probably two broods, as laying observed in Jun and Sept–Oct at site near Darwin (Northern Territory). Breeds as simple pair or in co-operative group with one or more helpers. Nest said to be composed of fur, grass and feathers, placed in hollow branch (“spout”) or trunk of living or dead tree, sometimes in stump; of five nests at site near Darwin, three in northern salmon gum and two in Darwin woollybutt, height above ground 3.6–9 m (mean 6 m); elsewhere, nests 3.7–9.1 m up; no estimates of territory size. Clutch 1–3 eggs, usually 2 (mean of eight clutches 2.1), slightly lustrous, light pink colour almost obscured by reddish-brown and purplish-red spots and blotches, intermingled with underlying markings of lavender-grey, predominantly at larger end; incubation probably by female alone, period unknown; no information on nestling period.

**Movements.** Preliminary observations suggest that species is sedentary within year-round all-purpose territory.

**Status and Conservation.** Not globally threatened. Locally common. Recorded densities 0.1–0.6 birds/ha. In most parts of range, habitat subject to regular burning, often annually, but effects of fires still unclear; densities are high in some woodland areas subjected to burning in early dry season (fires mild) or in late dry season (fires hot). The least-known member of its family in Australia.

**Bibliography.** Barrett *et al.* (2003), Blakers *et al.* (1984), Brooker, Braithwaite & Estberg (1990), David & Gosselin (2002b), Doerr & Doerr (2002), Franklin (1999), Higgins *et al.* (2001), Noske (1980b, 2006a), Pizzey *et al.* (2005), Schodde & Mason (1999), Simpson *et al.* (2004).

## Class AVES

## Order PASSERIFORMES

## Suborder OSCINES

## Family PARIDAE (TITS AND CHICKADEES)

- Small to medium-sized, plump passerines with short to moderate-length strong bill, strong legs and feet, and short to medium-length tail; soft plumage varying greatly in colour, including yellows, greens, blues, browns, black, greys and white in patches, rather than as streaks or spots.

- 9-21 cm.

- Neartic, Palearctic, Oriental and Afrotropical Regions.
- Most shrubby to wooded terrestrial habitats, from scrub to wooded savanna, carr, all types of woodland, and urban to rural parks and gardens.
- 9 genera, 56 species, 248 taxa.
- 1 species threatened; none extinct since 1600.

## Systematics

The family Paridae includes some of the most intensively studied bird species in the world. In recent years, more than one hundred scientific papers have been published annually on diverse aspects of parid biology. It is ironic, then, that significant developments in parid systematics are among the subjects covered by these papers. Indeed, so confusing has been the intrafamilial classification of the group that it is only in the last decade that any form of consensus has emerged. Before 1998, when the American Ornithologists' Union elevated the subgenera of the American crested titmice and chickadees to the level of full genera, respectively *Baeolophus* and *Poecile*, all except two atypical oriental species, the Yellow-browed Tit (*Sylviparus modestus*) and the Sultan Tit (*Melanochlora sultanea*), incidentally the smallest and largest parids respectively, were classified together in the single genus *Parus*. The AOU's decision, based on a clear morphological distinction between the two groups of North American parids, forced the vexed issue of the family's taxonomy into the spotlight. This was particularly because one Holarctic species, known as the Siberian Tit in the Palearctic and the Gray-headed Chickadee in the Nearctic, was now also represented under different generic names, *Parus* in the Palearctic and *Poecile* in the Nearctic, thus leading to an even more confusing situation. Furthermore, while the *Poecile* tits, meaning the "multicoloured" or "variegated" tits, form a clearly delimited group in Europe, with the Marsh Tit (*Poecile palustris*), the Willow Tit (*Poecile montanus*) and the Sombre Tit (*Poecile lugubris*), the delimitation of the genus farther east became less clear. It is this very problem of fuzziness around the edges of the former, expanded, genus *Parus* that caused the taxonomic conservativeness, or systematic inertia, in the first place.

The AOU's decision had significant taxonomic ramifications also for the *Baeolophus*, or "short-crested", titmice of the New World, because their relationships with the two crested tits of the Old World, now grouped in the genus *Lophophanes*, meaning "showing a crest", were far from clear. Again, a single species, the Bridled Titmouse (*Baeolophus wollweberi*), caused the problem, because, while atypical of the *Baeolophus* group in size and markings, its similarity in plumage, though not in size, to the European Crested Tit (*Lophophanes cristatus*) is striking.

Controversy over the intrafamilial taxonomy of the Paridae is not new. Indeed, the genera now adopted were first proposed, on the basis of plumage, in 1903, by C. E. Hellmayr, and were later

largely supported, as subgenera, by G. Thielcke on the basis of vocalization comparisons. To ornithologists familiar only with the European or North American avifaunas, the new taxa may have seemed reasonable, since, for example, a clear distinction can be made between the European *Poecile* species and the rest. It is when one casts the net more broadly, and is forced to assign such species as the Varied Tit (*Poecile varius*; formerly *Parus varius*) to a genus, that the challenge is encountered. An Oriental species, the Black-lored Tit (*Parus xanthogenys*) of India and the Himalayas, epitomizes the problem. This species, like the Yellow-cheeked Tit (*Parus spilonotus*) of Indochina, is about the size of a Great Tit (*Parus major*) and it exhibits a belly stripe and a nuchal spot, as do most species of *Parus* (in the narrow sense), but it also retains yellow cheeks into adulthood, a character that is atypical of *Parus* but not unusual in *Periparus*, the latter meaning "close to *Parus*". It has a distinct eyestripe, typical of *Cyanistes*, the "dark blue" tits, or of *Lophophanes*, and a black cap more typical of *Poecile*; the black feathers of the crown are drawn into a crest, as seen in *Lophophanes*, *Baeolophus* and some *Periparus* species, but not in *Parus*. In general appearance, the Black-lored Tit is a large, yellow-cheeked tit with a green back; it resembles the Green-backed Tit (*Parus monticolus*), with which it shares the character of a double wingbar, but differs in the possession of an eyestripe and a crest. Clearly, parid systematics could not be sorted out without independent evidence, and the consensus was therefore to lump the whole mess within the, albeit unwieldy, Linnaean genus *Parus* until such evidence appeared.

To add spice to this taxonomic mishmash, a long-standing dissatisfaction with the classification of a small passerine looking rather like a babbler (Timaliidae), and superficially resembling the ground-jays *Podoces* of the crow family (Corvidae), was resolved in 2003 by H. F. James and colleagues. Using extensive osteological and DNA evidence, these researchers showed that the taxon *Pseudopodoces humilis*, first described in 1871, in the genus *Podoces*, and given the English name of Hume's Ground-jay or Hume's Groundpecker, is in fact an aberrant tit, and it has been renamed as the Ground Tit. Subsequent study of the chemistry of its preen-gland secretions support this finding, thus showing it to be the world's second largest tit species, rather than the smallest corvid. The Ground Tit's evolutionary relationship to the rest of the Paridae, however, remains an issue for debate, because different analytical methods have yielded different conclusions (see below). It has also been proposed that the Fire-capped Tit

(*Cephalopyrus flammiceps*), traditionally placed with the penduline tits of the family Remizidae, may actually belong in Paridae, particularly in view of its habit of nesting in tree holes.

The independent evidence required to sort out the rest of the parids has come from DNA-sequencing, and has been published only very recently, in a series of papers. The most important of these, by F. B. Gill and colleagues, was published in 2005. These authors' affiliations, at the Academy of Natural Sciences, Philadelphia, the University of California and Louisiana State University, in the USA, indicate the scale of the project. Their work, based on the cladistic analysis of mitochondrial DNA sequences from 40 parid species, including *Pseudopodoces humilis*, provides the most objective basis yet for the assignment of taxa within this family, and gives considerable insight into the evolutionary history of the Paridae. It is sobering to consider that, just a few years ago, in 2001, most of the species currently included in the Paridae would have been lumped within the single genus *Parus*, and any statement of the relationships among them would have been very largely speculative. It is on the basis of the research by Gill and co-workers also that the British Ornithologists' Union accepted the Hellmayr nomenclature, so recognizing five genera for the six parid species found within the British Isles.

Contrary to early-twentieth-century arrangements, such as that by A. Wetmore, which considered the Paridae to be closely related to the Old World orioles (Oriolidae) and the corvids, *Pseudopodoces* notwithstanding, DNA evidence suggests an arrangement much closer to that proposed by most nineteenth-century systematists, such as S. F. Baird and R. B. Sharpe, and to the 1956 "Basel sequence" of E. Mayr and J. C. Greenway in their "corvids-last" classifications. Genetically, the Paridae form an evolutionary branch, or clade, and are sister-taxon to the penduline tits (Remizidae), with which they have often been grouped as a subfamily within an enlarged family Paridae. Earlier DNA-based classifications have indeed done this, so that the decision as to whether or not to combine them is not directed clearly by the DNA evidence itself. Together, the Paridae and the Remizidae, which on the evidence of genetic distance appear to have diverged about 7–6 million years ago, form a sister-group to other sylvioid families, most closely to the nuthatches (Sittidae) and the long-tailed tits (Aegithalidae). A division from the penduline tits implies an Old World origin for the Paridae, since the remizid tits are almost exclusively Old World, the Verdin (*Auriparus flaviceps*) of south USA and Mexico being the sole exception. Moreover, the family Paridae is most diverse in the Old World: all except one of the parid genera are represented there, and the

three most divergent taxa, namely, the Yellow-browed, Sultan and Ground Tits, are found there; in addition, the four species with the greatest subspecific differentiation, the Great Tit, with 34 subspecies, the Coal Tit (*Parus minor*), with 21, the Willow Tit, with 15, and the Common Blue Tit (*Cyanistes caeruleus*), with eleven, are all Old World species. Paridae is completely unrepresented in the Neotropical and Australasian Regions.

The phylogenetic evidence from an Old World origin is fully supported by the DNA evidence provided by Gill and colleagues' analyses. These show all the species currently treated within the Paridae as a clade, signifying that they are monophyletic, and assist to the three species of remizid included in the analyses for comparison. Gill and colleagues used two statistical methods in order to derive their phylogenetic "tree" (the "A tree" is the single most parsimonious tree, and the "B tree" the maximum-likelihood phylogram). Although these agree on the data (as far as described), they differ in detail at many other points, and there is no clear indication of which tree, if either, may be correct. In most of these cases, the discrepancy makes the difference to one's appreciation of the likely evolutionary path, but in a few cases this can be seen below. Differentiated early in the phylogeny of the Paridae, both trees are the Common Blue Tit and the Azure Tit (*Cyanistes cyaneus*). These form a clade in both, but in the A tree they are basal to the whole family, whereas in the B tree their differentiation occurs shortly after the separation from a more basal clade, which today contains the oriental monotypic taxa *Sitta sumatrana* and *Melanochlora*. The Common Blue Tit and Azure Tit clade is now identified formally as the genus *Cyanistes*. Although *Sitta sumatrana* and *Melanochlora* appear themselves to have diverged very early, it would be hard to find two more disparate forms in the Passeriformes, let alone among the Paridae. The similarity between the diminutive *Sylvioparus* and a leaf-warbler (*Phylloscopus collybitz* Kinglet (*Regulus*)) is also hard to ignore, and perhaps points at the earliest forms of parid. Unlike these *Sylvioparus* and *Regulus* genera, however, *Sylvioparus* exhibits a number of typically parid characteristics, including its voice, a strong sandy bill, blue-grey legs and feet, a hole-nesting habit, a hair-lined nest of moss, and the inclusion of seeds in the diet. All of these characters are shared with *Melanochlora*, and with most other parids. In the *Sylvioparus*–*Melanochlora* clade is basal to the Paridae, this suggests a possible Oriental or perhaps, even more specifically, a Himalayan origin for the Paridae: of the nine parid genera, only *Cyanistes* and *Baeolophus* do not occur in the Himalayas. This view may be further supported by the B tree's positioning of the monotypic *Pseudopodoces*, which is today restricted geographically to the

The evolutionary history of the Paridae is complex, so much so that many disparate groups were until recently lumped into a single unwieldy genus, *Parus*. The emergence of genetic analyses and molecular phylogenies provided the independent evidence required to subdivide *Parus* into several newly accepted genera. One of these, *Poecile*, contains 13 species, including the **Sombre Tit**, which lives in the open woodland, maquis, and orchards of south-east Europe and Asia Minor. Like most of its congeners, it is a study in brown, with a dark cap and bib, a stubby black bill and bluish-grey legs.

[*Poecile lugubris lugubris*, Bulgaria.  
Photo: Mike Lane]

Tibetan plateau, as a slightly more recent branch, yet still basal to all other parids except the *Cyanistes* clade. The A tree, however, differs significantly in its positioning of *Pseudopodoces*, placing it within the great clade of the new genus *Parus* as herewith defined.

Both trees indicate that a major division of the Paridae, which occurred about 5 million years ago, separated what were to become two great clades. One of these contains the further subdivisions now recognized as the four genera *Poecile* (chickadees), *Periparus* (coal tits), *Lophophanes* (Old World crested tits) and *Baeolophus* (New World crested tits); the other contains all species recognized as constituting the now restricted genus *Parus* (great tits). This major division neatly separates the seed-hoarding tits, many of which also excavate their own nest-holes, from the non-hoarding tits, none of which excavates its own nest-hole. For this reason, it is deemed logical that the genus *Baeolophus* be moved from its traditional position, near the end of the species listing, to a position immediately preceding *Parus*.

Within the seed-hoarders, the timing of division into the four extant genera differs between trees A and B, although both indicate that the Old World and New World crested tits form a clade. Following the A tree, this crested-tit clade split off first, and the remaining clade further divided into *Periparus* and *Poecile*. According to the B tree, on the other hand, the chickadee, coal and crested-tit clades originated at similar times. The two trees agree, however, that the further evolution of the crested-tit and chickadee clades involved invasions of North America about 4 million and 3.5 million years ago, respectively, and that the earlier invasion led to subsequent differentiation into the *Baeolophus* clade seen today in North America, presumably evolved from a form closer in appearance to *Lophophanes* species. Interestingly, again in both trees, the Bridled Titmouse, which so resembles the European Crested Tit, appears to be an older form within *Baeolophus* (see also Voice), while the "Plain Titmouse", now split further into the Oak (*Baeolophus inornatus*) and Juniper Titmouse (*Baeolophus ridgwayi*), and the Tufted Titmouse (*Baeolophus bicolor*), along with the Black-crested Titmouse (*Baeolophus atricristatus*), represent a later division into western and eastern forms, respectively. For its part, *Lophophanes* is today represented by a chiefly western Palearctic form, the European Crested Tit, and an Oriental form, the Grey-crested Tit (*Lophophanes dichrous*), the latter confined to the Himalayas, Myanmar and south China.

The genus *Poecile* is clearly differentiated into two major clades. One represents the North American invasion, which was

followed by differentiation into the seven modern-day chickadee species, while the Old World branch showed a clear division between Oriental and Palearctic lineages, the latter's members being more similar in appearance to the Nearctic *Poecile* species. One species, the Siberian Tit (*Poecile cinctus*), represents a return invasion of the Old World from the New World, since it is much closer, both genetically and in its more rufous plumage, to the Nearctic Chestnut-backed (*Poecile rufescens*) and Boreal Chickadees (*Poecile hudsonicus*) than it is to any Palearctic or Oriental species. The colonization of North America by the *Poecile* tits was followed by their differentiation into three further branches. The first of these contained the Black-capped Chickadee (*Poecile atricapillus*) and the Mountain Chickadee (*Poecile gambeli*), two species which form a sister-group to the second branch, the aforementioned *rufescens-hudsonicus-cinctus* clade. The third branch led to the Carolina Chickadee (*Poecile carolinensis*) and maybe also, according to Gill and colleagues' A tree, the Mexican Chickadee (*Poecile sclateri*). It is worth noting that, apart from the more or less non-overlapping ranges of the Boreal and Chestnut-backed Chickadees, the geographical ranges and patterns of allopatry and sympatry in the Nearctic *Poecile* species give little indication of the historical or evolutionary relationships among these taxa.

The Oriental *Poecile* species, consisting of the Rusty-breasted Tit (*Poecile davidi*), the White-browed Tit (*Poecile superciliosus*) and the enigmatic Varied Tit, are distinct in plumage, and would seem to represent either relatively early branches from the main Palearctic/Nearctic lineage or relict forms closer to the proto-*Poecile* ancestor. Both phylogenetic trees suggest that *P. superciliosus* and *P. varius* represent "deep" divisions from the main line, but *P. davidi* probably branched off later from the main Palearctic clade that includes the Marsh and Willow Tits. The systematic position of the Varied Tit has long been problematic. In their important review of the Paridae, S. Harrap and D. Quinn, following Thielcke and J. F. Clements, placed it with another enigmatic species, the White-fronted Tit (*Parus semilarvatus*) of the Philippines, in the subgenus *Sittiparus*. The recent DNA evidence, and the Varied Tit's habits of food-hoarding and nest-hole excavation, however, indicate clearly that this species is an atypical *Poecile*. Interestingly, its closest relative in both trees appears to be the Sombre Tit of the Palearctic, from which its lineage appears to have separated some 4 million years ago. DNA sequences have not yet been published for the globally Near-threatened White-fronted Tit, the behaviour and ecology of which are virtually unknown. In the absence of clear data, it may be safest for the time being to retain this species conservatively within the genus *Parus*.

The two principal Palearctic *Poecile* species, the Marsh and Willow Tits, are sibling species that separated some 3 million years ago. Their present-day distributions suggest that both were once widespread through the Palearctic Region, as indeed the Willow Tit still is, but that repeated periods of glaciation have influenced their ranges, since both species have relict populations, for example the race *brevirostris* of the Marsh Tit and the subspecies *songarus* of the Willow Tit, that presumably represent evolutionary events within former, more southerly, glacial refuges. This is most pronounced with the Marsh Tit, which exhibits a major disjunction in distribution between the Palearctic and Oriental Regions, these populations being separated by more than 1600 km.

Last of the four food-hoarding groups is that of the coal tits, which form a morphologically distinct genus, *Periparus*, centred on the Himalayas. Within the great clade of seed-hoarding tits, *Periparus* species are distinct in their generally small size, in possessing both a distinct nuchal spot and two wingbars, and in the fact that, in contrast to *Poecile*, *Lophophanes* and *Baeolophus*, none excavates its own nest-hole, this perhaps because the *Periparus* tits tend also to have a relatively fine bill. The genus has two main subclades. One contains the two other Philippine species, namely the Elegant Tit (*Periparus elegans*) and the Palawan Tit (*Periparus amabilis*), which Harrap and Quinn, as well as Clements, aligned with the Yellow-bellied Tit (*Periparus venustulus*) of China in a subgenus *Pardiliparus*. The second

*The White-browed Tit is an aberrant member of the genus Poecile. It is large, with a relatively long tail, conspicuous white supercilia and a fairly straight culmen to the upper mandible. On the evidence of morphology and genetics, this species is an early offshoot from the Poecile lineage. It is restricted to the mountains of China, where it breeds in dwarf montane shrubland comprising rhododendron, willow and buckthorn, usually above 3200 m. In the non-breeding season it moves into more heavily forested habitats, and descends to slightly lower altitudes.*

[*Poecile superciliosus*, Ruogai, Sichuan, China. Photo: Nick Athanas]

Until recently subsumed in *Parus*, the morphologically distinct genus *Periparus* contains seven species notable for their small size, pale nuchal spots, and relatively fine bills.

They usually have two wingbars, one on the median secondary coverts and the other on the greater secondary coverts. These bars are formed by small white tips to the covert feathers, producing a dotted impression quite different from the continuous bars seen in some other parids.

The most successful and best-known member of this group is the **Coal Tit**, a conifer specialist distributed across the Palearctic Realm from Western Europe to Japan and Taiwan. Much less well known is the **Rufous-vented Tit**, a denizen of montane broadleaf forests in the Himalayan zone.

This species resembles the Coal Tit in general pattern, especially the pale cheek patch, but differs in its rufous vent, jaunty crest and lack of wingbars. The nominate race is extensively cinnamon on the underparts, while the eastern race *beavani*, pictured here, is largely grey below.

In terms of morphology, the tit family is relatively homogeneous, with species varying mainly in size and colour. Almost all tits are small arboreal birds with strong, short or medium-length black bills, dark eyes, rounded wings and soft plumage. The two Old World species in the genus *Lophophanes* adhere to the general theme in terms of structure, as well as plumage. The better-known member, the **European Crested Tit**, has a crest and a black throat, features that recur in several parid groups. The crest—prominent, spiky and permanently raised—is black with broad white fringes to the feathers, creating a scaled appearance. This species is a conifer specialist in parts of its range, including Scotland, but inhabits broadleaf forest in much of southern Europe.

According to current taxonomy the European Crested Tit (*Lophophanes cristatus*) and the Grey-crested Tit are sibling species. However, it seems plausible that their similarities are superficial, that they are not each other's closest relatives, and that *Lophophanes* is polyphyletic. Further molecular and vocal analyses are needed to determine their true relationship. The Grey-crested Tit is common in high-altitude broadleaved evergreen, coniferous or mixed forests in the Himalayas and south China.

subclade houses the remaining four species, two of which, the largely Palearctic Coal Tit and the Himalayan Spot-winged Tit (*Periparus melanolophus*), are very closely related, are known to hybridize and, on the basis of DNA, may well be conspecific; the Himalayan subspecies *aemodius* of the Coal Tit is crested, and the Spot-winged Tit is distinctly so. A further branch within the non-Philippine subclade contains two sibling species. These are the Black-breasted Tit (*Periparus rufonuchalis*), found in the Himalayas and westwards to Turkestan, and the Rufous-vented Tit (*Periparus rubidiventris*), which occurs in the Himalayas eastwards to Myanmar and south China.

The non-hoarding tits contain the two remaining genera, *Parus* and *Cyanistes*, neither of which exists completely without controversy. Nevertheless, the DNA evidence presents both as distinct clades, although, as intimated above, the inclusion of the White-fronted Tit within *Parus* may be erroneous. For the 23 species of *Parus*, both of the phylogenetic trees presented by Gill and colleagues show a distinct split between the 15 Afrotropical species and the remaining eight, of which all but two, the Great and Turkestan Tits (*Parus bokharensis*), are Oriental species, although A and B trees differ on the origins of the Grey Tit (*Parus afer*) of southern Africa. The distinct plumage characteristics of the 15 Afrotropical tits were recognized by Clements and by Harrap and Quinn when placing them within the subgenus *Melaniparus*. It is a further great irony of parid research that, while the Great Tit has been described as the best-known avian species in the world, many of the Ethiopian and Oriental species of *Parus* are among the most poorly known. In some instances, for example, the nest has never been described, and for many of these species further details of breeding and social organization are unknown. Similarly, *Parus* presents the sparsest DNA dataset of any parid genus; material was available to Gill and his colleagues from only eleven of the 23 species, whereas all *Poecile*, *Lophophanes* and *Baeolophus* tits and all except one *Periparus* species were represented. Consequently, many details of systematics within *Parus* remain open to debate. The Great Tit itself forms a distinct, and relatively recent, grouping with the Turkestan Tit and the Green-backed Tit: the "great-tit clade". It is likely, however, that the relatively great diversity of forms seen across the 34 subspecies of the Great Tit disguises the fact that *P. major* may in fact be better treated as three spe-

cies, *P. major* in the Palearctic, *P. cinereus* in India, and *P. minor* in South-east Asia, the last two having songs differing markedly from those of *P. major*. The White-naped Tit (*Parus nuchalis*) may represent an earlier branching-off from this clade south of the Himalayas, but should probably be included within it. The Oriental forms, consisting of the Yellow Tit (*Parus holsti*), the Yellow-cheeked Tit and the Black-lored Tit, represent a distinct branch, separated from the great-tit clade some 4 million years ago. Within this, both of the phylogenetic trees presented by Gill and colleagues show *P. holsti* to be an earlier offshoot, which was recognized by Clements and by Harrap and Quinn as a distinct genus, *Machlolophus*, while *P. spilonotus* and *P. xanthogenys* are sibling species, as might be predicted from their plumages.

With material from only six of the 15 African *Parus* species available, these are the most poorly represented in Gill's phylogenetic trees. A constant distinction appears to lie between, on the one hand, the black-tit group formed by the Southern Black Tit (*Parus niger*) and the White-bellied Tit (*Parus albiventris*), which should also contain Carp's Black Tit (*Parus carpi*), the White-winged Black Tit (*Parus leucomelas*) and the White-shouldered Black Tit (*Parus guineensis*), and possibly the White-backed Black Tit (*Parus leuconotus*), but not the Dusky Tit (*Parus funereus*), and, on the other, the more rufous Rufous-bellied Tit (*Parus rufiventris*) and Stripe-breasted Tit (*Parus fasciiventer*), a group which presumably should include the Red-throated Tit (*Parus fringillinus*) and the Cinnamon-breasted Tit (*Parus pallidiventris*). The relationships among the African grey tits, consisting of the Somali Tit (*Parus thruppi*), the Miombo Tit (*Parus griseiventris*), the Ashy Tit (*Parus cinerascens*) and the Grey Tit, are, however, unclear. Of these species, which are reminiscent of the more cinereous forms of the great-tit clade, DNA was available only from the Grey Tit. In the A tree, *P. afer* forms an ancient sister-taxon to the Stripe-breasted Tit, whereas, in the B tree, it branches off early from the Oriental *holsti*-*spilonotus*-*xanthogenys* clade, after the latter split from the great-tit clade, raising the suggestion that the African grey tits may represent a separate invasion of Africa, evolving from a lineage distinct from that of the black tits. Under such an intriguing scenario, the subgenus *Melaniparus* used by Harrap and Quinn for the African species would be polyphyletic. It is therefore premature to recognize such a grouping. In this instance, geographical ranges add

useful insight, supporting the view that there are three clear clades. Within clades, species are largely allopatric and form a distributional mosaic. Hence, in the black-tit group, for example, the Southern Black Tit is found in the east of southern Africa, Carp's Black Tit in the west, the White-winged Black Tit in southern Central Africa with an isolated population in Ethiopia, and the White-shouldered Black Tit in West and Central Africa, while the White-bellied and White-backed Black Tits are largely of restricted range in East Africa. Similar allopatry is evident within the rufous-tit and grey-tit groups. Species belonging to different groups, however, are more often sympatric. Hence, the Miombo Tit occurs alongside both the White-winged Black Tit and the Rufous-bellied Tit in brachystegia (*Brachystegia*) woodland in west southern Africa, "miombo" being the Swahili name for brachystegia woodland.

The second of the non-hoarding tit genera is *Cyanistes*, which represents a genetically distinct and morphologically well-defined clade containing the western Palearctic Common Blue Tit and the eastern Palearctic Azure Tit, the "blue-tit clade". The two phylogenetic trees differ, however, in the branch position of this clade in relation to the rest of the family. In the A tree, the blue-tit clade is basal to the whole family, whereas, in the B tree, the split occurs after separation of the Oriental monotypic genera *Sylviparus* and *Melanochlora*, but perhaps not *Pseudopodoces*. Either way, this clade represents a very early split from the main parid lineage. The infraspecific systematics of these species, too, is controversial. Within the eastern forms, a distinction has usually been made between the yellow-breasted form *flavivinctus*, found in central Asia, and the rest. This has been known as the "Yellow-breasted Tit", but recent DNA analysis gives no support for its elevation to species level, and its geographical range suggests that it is a relict population isolated within a glacial refuge. Consequently, it is better treated as a subspecies of the Azure Tit.

Nor has the taxonomy of the Common Blue Tit escaped without issue. Although *C. caeruleus* is well defined within its main western Palearctic range, it is where it has extended into north Africa, and especially the Canary Islands, that the problems arise. The species is represented in north Africa by a well-defined sub-

species, *ultramarinus*, which exhibits the basic colour patterns of the species, except that the darker head markings, such as the crown and eyestripe, which in other races are blue or dark blue, are black and contrast strongly with the white forehead. This does not, in itself, present any problem, but the form appears intermediate between the nominate race and the four taxa found in the Canary Islands. The latter, comprising *teneriffae* on the central Canary Islands, *palmensis* on La Palma and *ombriosus* on El Hierro, both in the west, and *degener* on Fuerteventura and Lanzarote, in the east, have traditionally been included within *C. caeruleus*, although they display a number of distinct plumage characteristics, which are expressed in their most extreme form in *teneriffae*, which has uniformly blue upperparts and lacks white in the wing. Recent DNA evidence is again illuminating. To begin with, it indicates that the larger islands in the group, Tenerife and Gran Canaria, were probably invaded first, and that the other islands were colonized subsequently. Secondly, the genetic distance of these taxa from *caeruleus* suggests that they constitute a full species, the Canary Blue Tit (*Cyanistes teneriffae*), distinct from the rest of the blue tits. The position of *ultramarinus* then hangs in the balance. Does it represent a reinvasion of the continent from the Canaries, or the relict form from which the other Canary Islands taxa were derived, in which case the latter forms should be subspecies of it, or an independent later invasion of north Africa by *C. caeruleus*? This is all still contested, but such consensus as exists suggests that the most appropriate approach is to treat *ultramarinus* as a subspecies of the Common Blue Tit.

Discussion of the status of the blue tits in the Canary Islands reintroduces the subject of infraspecific taxonomy. While it appears that most of the species-level taxa result from branch nodes that occurred more than 2 million years ago, in the Pliocene, the subspecies generally owe their appearance to events that took place less than 2 million years ago, during the Pleistocene, the main recent period of glacial/interglacial sequences, or even in the post-glacial Holocene period, from 12,000 years ago until the present. Nonetheless, it should be noted that the currently recognized pattern of subspecific diversity shows no correlation with the presumed age of the species concerned. For example, relatively recent taxa, such as the Great, Coal, Marsh and Elegant Tits, exhibit high levels of geographical differentiation, with, respectively, 34, 21, eleven and nine subspecies. In comparison, such ancient lineages as those of the Ground and White-browed Tits have just one each. Investigation of the subspecific diversity of the parids reveals that it is not branch length but, rather, the degree of isolation, especially on islands, in mountain ranges and within glacial refugia, that predicts geographical differentiation. Fine examples of this are seen in the Far East: the Elegant Tit, endemic in the Philippines, has radiated into eight subspecies across this archipelago, and the Varied Tit, resident in Korea and the Japanese and adjacent islands, has likewise radiated into eight subspecies in this region. Of the 248 taxa currently recognized, a total of 49, or about 20%, can be defined as island forms. Here, a striking contrast is seen between the Old World taxa and those of the New World, since not one of these island subspecies is found within the Nearctic. There, glacial and montane isolation have played the major role in shaping the avifauna, as they have in the remaining Old World taxa. A good example of the latter is provided by the total of 21 subspecies of the Coal Tit.

The pattern of speciation through the influences of island and montane isolation and glacial and postglacial climate change is most striking in the complex currently classified as *Parus major*. This, the most diverse species in the family, contains 34 races, of which eleven are wholly island endemics. Traditionally, four sections have been recognized: the "nominate section" of green-backed, yellow-bellied Great Tits in the Palearctic contains twelve races, three of them island forms; the grey-backed, whitish-bellied "cinereus section" from south-western Asia to India and Indonesia houses 13 races, including three island forms; and the greenish-backed, white-bellied Great Tits of the "minor section", from eastern Asia and the Japanese islands south to Indochina, incorporate nine races, five of them island forms. The fourth section, *bokharensis*, is now recognized, on the basis of genetic evidence, as a full species, with three races of its own, and recent

Members of the genus *Baeolophus* are restricted to the Nearctic, where they are known by the common name of titmouse. This group contains five relatively large species, all of which are distinctly crested. The **Black-crested Titmouse**, which sports perhaps the most obvious crest in the genus, was until recently treated as a localized southern race of the Tufted Titmouse (*Baeolophus bicolor*). These forms intergrade across a narrow hybrid zone in Texas, but they differ in ecology. Further study is required to clarify their taxonomic status.

[*Baeolophus atricristatus atricristatus*, Roma, Texas, USA. Photo: Arthur Morris/ Birds as Art]

Despite recent shifts in taxonomy, *Parus* retains 22 species and therefore remains the largest genus in the family. The most familiar representative in many regions is the **Great Tit**, a widespread, abundant and vocal bird in Europe and Asia. It is fairly large, with white outer tail feathers and a stripe down the centre of the underparts, these features being common themes in its genus. The width of the black stripe is related to individual characteristics, including dominance, and also provides a means of distinguishing between the sexes. The bird on the right, with a broader stripe, is a male.

Lochman Transparencies]

analyses, using DNA evidence and hybridization studies, suggest that the other three sections should also be treated as such. Being largely isolated from one another by major landforms, such as the Himalayas, these probably represent early isolation events caused by, for example, glaciation.

The systematics of the Palearctic nominate section merit further comment. Although this section is differentiated into twelve subspecies, no fewer than ten of these either are isolated on islands (three races) or represent former glacial-refuge populations; of the latter, one is found south of the Mediterranean with others in Iberia, Greece, the Middle East, and southern Siberia into northern China. Across the vast area of the Eurasian continental landmass, from the Iberian mainland and throughout central, northern and eastern Europe eastwards through Siberia to Lake Baikal and south to the Altai and Sayan Mountains, a single subspecies, the nominate, is found. This lack of morphological diversification across so great an area suggests a rapid, presumably single recolonization of Eurasia following the last glacial epoch. This hypothesis, based purely on consideration of the subspecific biogeography, is supported by genetic evidence, which indicates that the northern populations had, indeed, passed through a recent genetic bottleneck and expanded rapidly from a narrow genetic base. A similar pattern has been described for the Common Blue Tit.

Hybridization is not known to be widespread within the Paridae. The hybrids hitherto described involve just 19 of the 56 species presently recognized. Furthermore, the validity of several of these is uncertain, and in only seven species pairs, involving 13 species, are hybrids thought not to be rare. None of these more frequently hybridizing pairs involves an intergeneric cross. There are three *Poecile* pairs, namely Willow and Siberian Tits, Willow and Varied Tits, and Carolina and Black-capped Chickadees; one *Periparus* pair, Coal and Spot-winged Tits; two *Parus* pairs, Rufous-bellied and Cinnamon-breasted Tits (not proven) and Great and Turkestan Tits; one *Cyanistes* pair, Common Blue and Azure Tits; and one of *Baeolophus*, Black-crested and Tufted Titmice. In three of these cases, those of the Carolina and Black-capped Chickadees, the Coal and Spot-winged Tits and the two titmice, clear hybrid zones have been identified, and species limits have been contested for many years. In two other cases, the Great Tit / Turkestan Tit and the Blue Tit / Azure Tit, hybridiza-

tion seems to occur periodically when one species extends its range into that of the other, such as happens following the Azure Tit's westward range expansions during very cold winters. Hybridization between Great and Turkestan Tits is thought to occur because of human-induced environmental changes that have favoured incursion by Great Tits. It is possible that human activity, and especially the provision of nestboxes, may have encouraged some of the less likely hybrids, especially intergeneric ones, that have been reported. For example, Great Tit hybrids with the Common Blue Tit, the Coal Tit and the Marsh Tit have been reported, but all are known to be very rare. All of these species will use nestboxes, and the tendency for Great Tits to evict pairs of other species during egg-laying and to take over their nests sometimes results in their raising a few chicks of the other species in their nests. The fate of these adoptees is unknown, but they usually fledge successfully, and the issue of what species they will subsequently prefer as their mate may therefore arise. Whether or not these intergeneric hybrids result from such a scenario is pure speculation, as must be the cause of any of the other rarer hybrids that have been reported, albeit with varying degrees of certainty. These include Marsh Tit × Willow Tit, Coal Tit × European Crested Tit, Coal Tit × Willow Tit, Carp's Black Tit × Southern Black Tit, and Tufted Titmouse × Black-capped Chickadee.

### Morphological Aspects

The genetic distances reported for the Paridae imply that it is a relatively old taxon (see Systematics) which appeared some 7–6 million years ago, and that the major branches of its phylogeny are also more than 2 million years old. This finding is particularly remarkable because it is in no way reflected in the morphological diversity within the group. Apart from the three monotypic genera *Sylviparus*, *Melanochlora* and *Pseudopodoces*, which include both the largest and the smallest parids, Paridae constitutes one of the most conservative avian families in terms of general morphology. For example, although its members range between 9 cm and 21 cm in length, exclusion of the monotypic genera reduces this to 10–16 cm; of the 56 species, 52, or 93%, are between 11 cm and 16 cm long, and 39, or 70%, lie within the length range 12–15 cm. In mass, parids range from 5 g to 49 g, the range

becoming 7–29 g when the monotypic genera are disregarded, but the fact that 85% of the variation in bulk, expressed as the cube-root of mass, can be predicted from the overall size is itself an indication of the general conformity of structure in the family. Its members differ little in the relative length of the bill or the tail.

Apart from size, parids vary morphologically mainly in plumage coloration. The general structural theme, upon which there is relatively little variation, is of a small to medium-sized passerine with a strong, short to medium-length, typically black bill, a dark eye and soft plumage; the short to medium-length, rounded wings contain ten primaries, six secondaries and three tertials, and the tail, which is typically square-ended, has twelve rectrices. The tarsus is of moderate length. The legs and feet are generally bluish-grey, and are strong, as they are in many instances required to support the bird while it is hanging upside-down (see General Habits), and they are frequently used as a means of restraining or stabilizing food items (see Food and Feeding). Plumage colours include black, white, greys, reds, browns, greens, blues and yellows. The plumage is typically coloured in "blocks" that more or less coincide with feather tracts, such as the crown, the cheek, the throat, and so on, because most feathers are uniformly coloured. Frequent exceptions to this are found in the remiges and rectrices, and the wing-coverts, which on many species carry a white tip, forming a spot. Spots elsewhere in the plumage are rare, and are absent from the main body tracts, and no parids display any streaks. Tits are sexually monomorphic, although females often present a slightly paler or less contrasting version of the male plumage.

Although the tits vary widely in colour, this plumage variation tends to be "themed" within genera, and may be highly conservative within a genus. Nowhere is this more apparent than among the 13 *Poecile* species, twelve of which, ranging in size from about 11 cm to 15 cm, are small and grey to brown, paler on the underparts, which are generally buff to white, and have a brown or black cap and bib, the latter of which may be small or extensive, joining the black bill and separated by paler cheeks that match, or are paler than, the colour of the underparts. *Poecile* tits typically lack wingbars and, apart from the Carolina and Black-capped Chickadees, have no white in the tail, although the wing feathers may be paler-edged on the outer web and, as in the *hudsonicus* group, slightly paler-tipped; in the "standard" *Poecile* theme, there is no nuchal spot. The exception to this general theme among members of the genus *Poecile* is the Varied Tit, which, while showing a number of the standard charac-

ters, has a distinct nuchal spot that matches the colour of the forehead, which itself is concolorous with the cheeks. The underparts of this species are of a rich rufous or chestnut colour, and, although reds are not uncommon in *Poecile*, especially in the Nearctic *hudsonicus* clade, the whole pattern is very much more reminiscent of that of the Rufous-vented Tit, which itself is atypical of its genus, *Periparus*, in lacking wingbars. It is this possession of largely genus-specific characters such as nuchal spots and wingbars by one or two members of other genera that so bedevilled attempts to classify parids before DNA evidence became available (see Systematics).

Like the Varied Tit, the nominate race of the Rufous-vented Tit has rich rufous underparts, in this case more cinnamon than chestnut. Dark underparts of this kind are present on several other *Periparus* species, including the Black-breasted Tit, a close relative of the Rufous-vented Tit, and the Spot-winged Tit. The lack of wingbars, however, is atypical of *Periparus*, and is a feature of only one other member, the Black-breasted Tit. The typical *Periparus* pattern shows two clear wingbars, one on the median secondary coverts and the other on the greater secondary coverts; these are formed by white tips, giving a spotted appearance, rather than the continuous bars of other genera. Apart from this, and the presence on some species of a crest, especially in Himalayan taxa, the *Periparus* theme recalls that of *Poecile*. Other differences from *Poecile* are that *Periparus* tits always exhibit a nuchal spot, the bill is typically thinner, and the birds are smaller in overall size, at 10–13 cm. The cheek colour of *Periparus* generally matches, or is paler than, the underparts, which are generally rather rufous. Important exceptions to this are the two Philippine species, the Elegant and Palawan Tits, which have yellow underparts. In the case of the Elegant Tit, the underparts match the cheek colour. In the Palawan Tit, however, the whole head, comprising the cap, the cheeks and the bib, is black, a pattern that is otherwise exhibited only by the Sultan Tit and a very localized British morph of the Great Tit, apart from the essentially all-black African tits and the White-fronted Tit. The Palawan Tit is exceptional also in the male's possession of a yellow mantle, which contrasts with the dark wings, the latter having two bold white wingbars.

In several respects, the plumages of the genus *Periparus* form a bridge to three other genera, two of which are, like *Periparus* itself, hoarders, the other being a non-hoarder. Some *Periparus* are crested, a feature shared with *Lophophanes*, *Baeolophus* and some *Parus*, and with the last-mentioned, especially, *Periparus*

Prominent crests are unusual features amongst *Parus* tits, but a recurring theme in the *Paridae*. Indeed, one general characteristic of the family is that certain morphological traits—including crests, pale cheeks, nuchal spots, dark throat patches and black chest stripes—reappear seemingly at random, making the delimitation of genera more challenging. The **Yellow-cheeked Tit** is an Oriental species, of montane forests from the Himalayas to Vietnam. Little is known about its ecology and breeding behaviour, but it is thought not to hoard its food or excavate its nest-hole.

[*Parus spilnotus*  
subviridis,  
Thailand.  
Photo: Morten Strange]

The main radiation of Parus tits occurs in the Afrotropics. Here, 15 species are currently recognized, many of which are essentially black with patches of white or rufous. This characteristic has given rise to the common name "black tits", while the entire group is sometimes separated into the subgenus *Melaniparus*. The white or rufous appears in different species on different parts of the body, usually on the wings, belly, mantle or iris. In the case of the **White-winged Black Tit** almost the entire wing is white. The nominate form, pictured here, is endemic to Ethiopia.

[*Parus leucomelas*  
*leucomelas*,

Unlike many African parids, the **Somali Tit** is not black. It approaches the Great Tit (*Parus major*) in pattern, although it lacks the yellow or green pigmentation of its more familiar relative. Species with similar plumage patterns are distributed spottily throughout Africa from Somalia in the north to Cape Town in the south. It is possible that these species are more closely related to the typical Parus tits, and that the true "black tits" deserve a genus of their own.

The Somali Tit is distributed in East Africa from Somalia to Tanzania, where it inhabits dry thornscrub, open acacia woodland, and gallery woodland.

[*Parus thruppi*.  
Photo: Jürgen Schneider]

shares the distinct nuchal spot and the presence of up to two distinct wingbars. *Lophophanes* and *Baeolophus* species display no wingbars, but they do have a distinct crest, even in juvenile plumage. The two Old World crested tits, in the genus *Lophophanes*, are reminiscent of *Periparus* also in their small size, 11.5–12.5 cm, and rather fine bill. In these characters they differ strikingly from the larger New World crested tits in *Baeolophus*, which are 11.5–16 cm long and possess a strong, stout bill. In both the Old World and the New World crested-tit genera, the plumage tends to be uniformly brown or bluish-brown above, with the underparts paler, often slightly rufous or sometimes, as in some *Baeolophus* species, with rufous just on the flanks. The exceptions to this pattern are, in the Old World, the European Crested Tit and, in the New World, the Bridled Titmouse, both of which exhibit what are, by parid standards, complex head markings involving a dark or "patterned" cap and crest, and a dark eyestripe that joins up with the dark tips of the ear-coverts. A further dark inner "frame" of the face is formed on both species by black feathers that border the nape and mantle. On the European Crested Tit, this frame joins up with the distal corners of the bib, whereas, on the Bridled Titmouse, it is the ear-covert frame that meets the bib. On the European Crested Tit, at least, the pattern on the rear head and hindneck, when the crest is raised, forms a "false face", a very convincing replica of the face pattern as seen from the front. The purpose of this may be to confuse predators.

The presence of an eyestripe is generally uncommon in the Paridae. The character occurs only nine times in the whole family, and can be considered a generic character only in *Cyanistes*, although a weak stripe may be present in both *Lophophanes* species. The *Cyanistes* tits form a well-defined group in terms of general plumage pattern, but here, again, they are difficult to characterize generically, and such plumage details as wingbars, which seem almost to define *Periparus* and *Parus*, are found to differ in occurrence among subspecies within a single species of *Cyanistes*, as demonstrated by the island races of the Canary Blue Tit. It is in the genus *Cyanistes* that blue becomes a dominant colour in the upperparts, although it varies greatly in intensity, from the pale grey-blues of the Azure Tit to the intense deep colours of the Canary Blue Tit, in line with Gloger's Rule. All have a white forehead, which, in the case of the Common Blue and Canary Blue Tits, continues as bold white supercilia that join above the

nape and separate the dark eyestripe from a blue to almost black cap. As with the crested tits, the face of the two last-mentioned species appears framed by a dark border running from the eyestripe behind the eye and around the ear-coverts and cheek to the small bib; this is the equivalent of the outer frame of the crested tits. Much of this patterning is absent in the Azure Tit, the whole head of which is white, apart from a thin eyestripe linking dorsal to a partial cheek border, which does not extend forwards beyond the line of the closed wing. The bill of *Cyanistes* is among the strongest of any in the family, as its short length, coupled with its relatively great depth, allows for a powerful bite at the

The genus *Cyanistes* contains a genetically distinct and morphologically well-defined trio of species, which together form the "blue-tit clade". These species are distinguished by their small size, active foraging habits, and bright blue plumage on wings, tail and cap. The familiar Common Blue Tit (*Cyanistes caeruleus*) of Europe is replaced to the east by the **Azure Tit**, an angelic-looking species with much white in the plumage, particularly in the wings and tail. These two forms regularly interbreed where their ranges meet. The bird pictured here can be aged as a juvenile by its relatively dull cap and the yellow flange at the gape.

[*Cyanistes cyanus tianschanicus*,  
Tanga, Kyrgyzstan.  
Photo: Hanne & Jens Eriksen]

bill tip. Several small plumage details apparent in *Cyanistes* are reminiscent of characteristics of the other great non-hoarding genus, *Parus*. The yellow underparts, present on the Common Blue and Canary Blue Tits, and hinted at in the yellow-breasted races of the Azure Tit, recall the yellow underparts of the Palearctic and some Oriental *Parus* species; in addition, the hint of a belly stripe on the Common Blue and Canary Blue Tits, and the suggestion of a nuchal spot on the former, are both pointers for *Parus*, as also are the white outer tail feathers of the Azure Tit.

Within both *Parus* and *Cyanistes*, there is a perception that variation among species in plumage coloration is not so much a matter of turning colours on or off but, rather, one of turning up the hue, brightness or contrast. Hence, if the Azure Tit is a monochrome Common Blue Tit, the Canary Blue Tit is a high-intensity version of the Common Blue Tit. In *Parus*, this perception occurs not only with regard to the importance of yellow and green in the plumage, but also in the extent of melanin. Looking first at the green-and-yellow plumages, and taking the Great Tit as a standard, the act of turning up the hue on this produces the Green-backed Tit of the Himalayas and south China, whereas turning down the hue gives the "*Parus major minor* group" and the Turkestan Tit, then the "*Parus major cinereus* group", and finally the grey tits of the African "*Parus thruppi* group". Playing with the extent of black in the plumage leads from the all-black plumaged African tits of the "*Parus niger* group", though these also vary greatly in the extent of white in the wing, through the Oriental White-naped Tit, with its black upperparts, and Green-backed Tit, in the race *legendrei* of which the male's belly stripe has expanded almost to the full width of the underparts, through to the Great Tit group.

Although, as mentioned earlier (see Systematics), two Oriental species, the Black-lored and Yellow-cheeked Tits, carry a number of traits that are atypical of *Parus*, three distinct plumage themes can be defined for *Parus*. These are the black-tit type, the rufous-bellied-tit type and the great-tit type, corresponding largely, but not exactly, with the black-tit, rufous-tit and grey-tit clades, respectively (see Systematics). The black-tit type includes the White-shouldered Black, White-winged Black, Southern Black and Carp's Black Tits and the White-bellied Tit, which form a well-defined grouping. In terms of plumage alone, this

may include also the White-backed Black and the Dusky Tits, although the evolutionary and systematic relationships of these two species are unclear, and their similarity in plumage to the other African black tits may be due to convergence, rather than to a common evolutionary history. The basic pattern displayed by all of these tits consists of a predominantly black plumage, with white in the wing varying from none in the White-backed Black Tit, which has a pale brownish mantle, through distinct wingbars and carpal patches, as in the southern African species, to the extensive white patches on the shoulder, wing-coverts and outer remex webs of the White-shouldered Black Tit. In the White-bellied Tit, the belly, flanks, vent and undertail-coverts are also white. Apart from the White-shouldered Black, White-backed Black and Dusky Tits, these species also exhibit white in the outer rectrices, a character found in all except four of the 23 *Parus* species, thus in all other African members of the genus. In addition to its lack of white in the tail, the White-shouldered Black Tit is unusual in the Paridae in having a distinctive whitish or yellow iris, a character shared with just one other tit, the Rufous-bellied Tit, which has a yellow iris. The juvenile's iris is grey, the juveniles of the latter species having a brown iris. In the rest of the family, iris colour is typically dark brown in juveniles, becoming slightly more reddish in adulthood, but in all cases being so dark that these distinctions can be recognized only in the hand; in the field, the eyes appear black. The significance of pale irides apparently evolving independently in two lineages of African *Parus* is unknown, but eye colour could certainly indicate an individual's age and therefore be of some significance for social behaviour.

Unlike the black-tit type, the rufous-bellied type, comprising the Rufous-bellied, Cinnamon-breasted, Red-throated and Stripe-breasted Tits, exhibits a contrast between darker, generally grey, upperparts and rufous underparts. All have two wingbars, formed by white tips and edges on the greater and median wing-coverts, and bold white edges on the otherwise darker tertials, as well as a variable amount of black on the head. The extent of black on the head varies from a reduced cap, as on the Red-throated Tit, to a hood, as on the Rufous-bellied and Cinnamon-breasted Tits, and to a hood extended into a ventral stripe, as shown by the Stripe-breasted Tit. The last-mentioned species is the least ru-

fous of the group, and, with its greenish-grey mantle and belly stripe, it grades in appearance towards the great-tit type, represented in Africa by the grey tits.

In contrast to the previous two *Parus* types, which lack white cheeks and a nuchal spot, all members of the great-tit group possess these characters. The African grey tits generally share with the rufous-bellied tits the bold wing patterning formed by pale covert edges. This is much reduced or absent in the Palearctic and Oriental *Parus* species, although the bold tertial edges are generally present. The general plumage theme of the great-tit type is of darker upperparts of grey, green or black, paler underparts of white or grey to yellow, a black cap extending from the bill to the nape, and a similarly coloured shield-shaped bib which may extend ventrally into a belly stripe, this stripe tending to be more complete on the Palearctic and Oriental species than on the African ones. The cheeks are typically white, contrasting with the rest of the plumage, although on the Miombo, Yellow-cheeked and Black-lored Tits, as well as the Yellow Tit, they match the colour of the underparts. The cheeks are also typically framed by a black border joining the bib to the cap at the nape, but this is incomplete on several African and Oriental species. The Yellow Tit is exceptional in its cap pattern and colour and in its lack of a bib, although a black vent contrasting with otherwise yellow underparts hints at a belly stripe.

In general, *Parus* species are larger than other tits, ranging in length from 11.5 cm to 16 cm, 80% of the 23 species being 13–16 cm long. In this respect they are reminiscent of *Baeolophus*, which may represent their ecological equivalents in the Nearctic. The larger size is a characteristic also of *Pseudopodoces*, the Ground Tit, which may be closely related to the great-tit group. Its plumage recalls that of the great tits in its darker upperparts, its pale nuchal spot and its distinct cap extending to the base of the bill, and in its white outer tail feathers. On the other hand, it differs markedly from them in the lack of any bib or belly stripe and in its brownish, rather than grey or yellow/green, general cast.

The problem of traditional parid systematics, then, is that plumage characters that seem almost to define infrafamilial taxa do not quite do so. The wingbars, eyestripes, nuchal spots and white outer tail feathers crop up in odd species here and there, irrespective of generic affiliation. This undoubtedly reflects the great age of the family and, therefore, the fact that many of these

species represent relicts from older taxa; frequently, the isolation events that resulted in speciation are indiscernible. Given that many plumage characters do transcend generic boundaries, however, we may consider, and perhaps speculate a little on, the functions of these plumage characters. To do this, we must take into account the sociality of the parids (see General Hints), since most are highly gregarious and associate, at least for part of the year, with conspecifics and/or join mixed-species flocks. The head pattern of most parids, with a cap, eyestripes, pale cheeks, a bib and so on, conveys information on social status, condition and, in conjunction with posture, to some extent also intention, because, in "radiating" from the bill base, they indicate accurately the angle of the bird's head in relation to the viewer.

In general, social status among the tits is strongly determined by sex, males dominating females, and age, adults dominating first-years and juveniles. Plumage characters that indicate sex and age, therefore, implicitly provide information on the status of the individual and tend to result in potential conflicts being resolved, without escalating to harmful agonistic interaction such as fighting. With many species, females resemble males in their essential plumage pattern, but the intensity, or chroma, may be duller and less contrasting. This is true of *Parus*, *Cyanistes* and *Periparus* tits, but much less so of *Poecile*, *Lophophanes* and *Baeolophus* and perhaps also the monotypic genera, in which the sexes are virtually identical in plumage. This difference in the degree of sexual dichromatism appears to reflect the social organization of these species, since many tits in the latter genera pair for life and defend group and/or year-round territories, whereas species in the first three genera tend to re-pair each year and establish new territories, although both the territory and the partner may be the same as in the previous year. Irrespective of social organization, however, males of most species are larger than the females, a fact that probably contributes to their social dominance. Although the degree of size dimorphism may vary even within species, from one habitat to another, the sexual size difference, measured as wing length, of British *Parus*, *Periparus*, *Poecile* and *Cyanistes* species occurring at the same woodland site was about 4% of the male's size, irrespective of the large differences in absolute size of these species. The small sexual differences in plumage pattern, such as bib size, belly-stripe width and ultraviolet Vire-

The **Canary Blue Tit** has traditionally been lumped with the **Common Blue Tit** (*Cyanistes caeruleus*), but its isolated range and divergent mitochondrial DNA suggests that it is better treated as a separate species. Genetic data indicate that the large islands of Tenerife and Gran Canaria were probably colonized before smaller islands in the Canary archipelago. The species differs from European forms of the Common Blue Tit in its bluer back, darker cap, and reduced white in the wing, and thus more closely resembles North African forms. Further research is necessary to clarify the taxonomic arrangement of these forms.

[*Cyanistes teneriffae palmensis*, Los Tilos, La Palma, Canary Islands.]

Photo: Johannes Ferdinand]

The **Yellow-browed Tit** is an aberrant parid, and sole occupant of the genus *Sylviparus*. With its tiny size and uniform greenish plumage, it resembles a leaf-warbler (*Phylloscopus*) or a kinglet (*Regulus*), perhaps hinting at the evolutionary origins of the Paridae. Unlike those groups, however, the Yellow-browed Tit is a typical parid in several morphological and behavioural features. It has a stubby bill, blue-grey legs and feet, agile foraging behaviour, and hole-nesting habits. It is found from the Himalayas to south China and northern Indochina, with an isolated population in the Da Lat Plateau of southern Vietnam.

flectance of the cap of *Periparus*, *Parus* and *Cyanistes*, respectively, concern characters that are known to be sexually selected and to indicate, by providing an honest signal, various aspects of the individual bird's fitness or condition.

As in the female plumages of these species, such characters are typically absent or greatly toned down in the juvenile plumages. Hence, in juvenile *Periparus*, the bib is either much reduced and diffuse or "washed out", as in the Coal and Spot-winged Tits, or absent altogether, as in the Elegant and Palawan Tits. A similar tendency towards reduced bib contrast is seen in young *Poecile* tits, although a small bib is usually present. The belly stripe of adult *Parus* species of the great-tit type is much reduced or absent on the juvenile, as also is the facial frame. Black plumage components, such as the cap and the bib, have a greenish cast which, together with pale yellow cheeks, presents a much less contrasting appearance than that of the adult. In the genus *Cyanistes*, the blue UV-reflective cap of the adult Common Blue and Canary Blue Tits is replaced in juvenile plumage by a dull greenish cap, in addition to which the bib is absent, the facial frame is much weaker, and the white forehead, supercilium and cheeks are picked out in yellow, giving the juveniles, as in *Parus* and most *Periparus* tits, a much less contrasting and, perhaps, less confrontational appearance. The greater presence of yellow in the plumages of juvenile *Parus*, *Periparus* and *Cyanistes* may be adaptive in reducing conflict, because the juveniles, since they carry no secondary sexual characters, avoid the triggering of territorial confrontation; their plumage represents a sort of passport enabling them to move freely between territories during the exploratory phase, when they are first independent of their parents. Parid juvenile plumages may also be more cryptic, providing the birds with better camouflage from predators during the time in their life when they are most vulnerable. It is interesting that these age-related plumage differences are generally not apparent in *Poecile*, *Lophophanes* and *Baeolophus* species, which may have more protracted post-fledging periods of juvenile dependency. It is also worth speculating on whether the plumages of some, especially Oriental, *Periparus* and *Parus* species, in which the adults have extensive yellow on the underparts, including the cheeks, have evolved

through neoteny, the process by which juvenile traits are retained into adulthood.

After the post-juvenile moult, the secondary sexual characters are present, although they may still be less intense than they will be after the first full post-breeding moult. Apart from these characters, most of the known age-related plumage differences relate to those feather tracts of the wing and tail specifically changed in the post-juvenile moult, and are evident in the contrasts between moulted and unmoulted feathers. The moults of *Parus*, *Cyanistes*, *Periparus*, *Poecile*, *Lophophanes* and *Baeolophus* are essentially similar in extent, in that juvenile remiges, primary coverts and a variable number of outer greater coverts are retained; in the last four of those genera, however, the colour of the adult feathers may appear to the human eye to be so similar to that of the juvenile ones as to provide no useful clue to age, although this does not necessarily mean that the birds themselves cannot see a difference. A few examples of the way in which first-years differ from adults may be instructive. In the genera *Parus* and *Cyanistes*, the retained juvenile primary coverts of the nominate race of the Great Tit and those of the Common Blue Tit are green, and contrast with the blue lesser and median coverts, whereas the adult has these parts of the plumage all of the same colour. In *Periparus* species, any retained juvenile greater coverts contrast with newly grown ones. With *Poecile*, *Lophophanes* and *Baeolophus* tits, the shape of the tail feathers is the best guide to age, first-years having narrower and more pointedly tipped rectrices than those of the adults, which are broader and more rounded. The extent of white in the outer rectrices may be useful in ageing some Nearctic *Poecile* species, and the colour of the roof of the mouth, blacker in the adult and greyer in the juvenile, may be useful for some *Baeolophus* tits.

Apart from any crypsis that they may provide, parid plumages also signal much about the individual wearing them. The pattern of the plumage is not generally changed through feather wear, but any worn plumage will appear duller and/or sun-bleached, and carotenoid-pigmented plumage is known to wear more rapidly than does melanin-pigmented plumage. This may be why badges, such as bibs, belly stripes and similar markings, are usually melanin-based. An important exception to the general picture is provided by the Dusky Tit. This species has whitish or greyish fringes on many wing-coverts and the tertials, and these are lost with wear. The importance of plumage wear, for example in signalling an individual's condition, has been little explored for the tits, and its significance to the Dusky Tit is unknown. In relation to age and sex, the signalling value of the plumage has already been described, but recent work on the Great Tit reveals that carotenoid-based plumage may also indicate an individual's condition in a sophisticated way. The principal yellow pigments in tits are lutein, zeaxanthin and, to a lesser extent, cryptoxanthin. The first of these is obtained chiefly from caterpillar prey, and the yellowness of the plumage appears to be directly proportional to the quantity of lutein in the feather. Since this is related to the diet available to the bird during the moult period, non-genetic differences in yellowness are found between populations inhabiting sites that differ in caterpillar abundance. Hence, yellow hue represents a complex trait that integrates information on diet, habitat quality and foraging ability of the individual. The feather's structure, however, is also important in determining the colour presented, and this has been found to be correlated both with the bird's relative mass, which is a simple measure of condition, and with the saturation of colour presented. Furthermore, the lightness of plumage may be related to the quantity of zeaxanthin present, and may indicate parasite load. In combination, therefore, the hue, the colour saturation and the lightness of the plumage may indicate territory quality, nutritional status and even the parasite load of the individual. It is worth noting also that Great Tits of the nominate race and subspecies *newtoni* that moult in captivity, deprived of dietary lutein, are grey, strongly reminiscent of the Turkestan Tit and the *cinereus* types of the Great Tit, and thereby raising questions about the genetic basis of the plumage differences between these taxa.

It appears, then, that the great diversity in plumage patterns seen in the Paridae can, to some extent, be predicted from knowledge of the birds' social behaviour and trophic ecology. Simi-

*The largest member of the family is the Sultan Tit, which weighs in at more than double the figure of many relatives. Its conspicuous foraging habits, loud voice, striking black and yellow plumage and flamboyant crest make it one of the most conspicuous and unmistakable birds of South-east Asian temperate forests. The plumage is a beautiful silky texture, and the crest is so long as to be floppy. The species occurs from the Himalayas to south-east China, Vietnam and Peninsular Malaysia.*

[*Melanochloris sultanea flavocristata*, Peninsular Malaysia. Photo: Morten Strange]

In addition to genetic factors, a number of important determinants of body size have been identified for several parid species. Most of these ultimately relate to the quantity and quality of food delivered to the growing chick. Body size, however, also varies geographically both among species within the same genus to some extent, and, more clearly, among individuals within the same species. In both cases, the variation is consistent with Bergmann's Rule, which predicts that individuals should be larger, on average, within populations inhabiting colder climates. Among

Holmes]

Almost all parids are arboreal birds, and as such they inhabit a range of forested and semi-forested habitats. Many live in broadleaf or mixed forests, while a few are conifer specialists, at least in parts of their range. The **Coal Tit** is one of the latter. In some regions it lives almost exclusively in spruce (*Picea*) forests, while in others it inhabits forests of pine (*Pinus*) or larch (*Larix*). In drier regions it relies on juniper, cedar, hemlock or birch, and in western Europe it thrives even in heavily modified habitats such as intensive conifer plantations and suburban gardens. Pairs of Coal Tits even defend territories around small clusters of pines or yews in urbanized city centres. The preference for conifers in this species runs deep: if a captive bird is offered the choice of two twigs, one of a pine, the other of an oak (*Quercus*), it will preferentially select the pine twig as a perch.

Low-stature forests are home to several parids, including the **Bridled Titmouse**. This species is distributed from the southern USA, in Arizona and New Mexico, to Oaxaca in southern Mexico. Throughout this region it lives in a variety of drier forests, including oak (*Quercus*), pine (*Pinus*) and juniper (*Juniperus*) forests in the montane zone, and dense scrubby forests at lower altitudes. In Arizona, for example, it breeds in low-lying areas with a growth of willows (*Salix*), cottonwood (*Populus*) and mesquite (*Prosopis*).

[*Baeolophus wollweberi phillipsi*, Madera Canyon, SE Arizona, USA.

Photo: Dave Maslowski/Maslowski Productions]

the genus *Remiz*, whereas in corvids it attaches to the maxilla or to both the maxilla and the jugal arch. Of 13 cranial characters listed, one is a distinct arrangement of the nasofrontal hinge, the hinged bone joining the base of the upper mandible to the cranium: in the Paridae, the maxilla abuts the frontal bone at the nasofrontal hinge, and the hinge is a straight cartilaginous band, allowing retraction of the upper mandible (rhynchokinesis) in an exaggerated forceful bite, whereas the corvid maxilla overlaps the frontal bone at the hinge, and the hinge is irregular in shape and restricts rhynchokinesis. Seven characters listed for the mandible include the fact that, in corvids, a bony crest extends from the medial process to the lateral condyle, creating a flat surface of bone in the posterior view of the mandible; this crest is absent in parids. Two characters of the hyoid skeleton are presented, both of which clearly distinguish parids from corvids. Four characters of the vertebral column are identified, including moderately developed to well-developed paired bilateral fossae on the ventral faces of many of the synsacral vertebrae in the Paridae, these being weak or absent in the Corvidae. One character relates to pneumatic foramina on the dorsal surface of the sternum, which in most parids consists of a single opening, or sometimes several openings, near the rostrum. This differs from the character state both in *Pseudopodoces*, in which foramina are absent, and in the corvids, in which they are extensive, especially across the cranial third of the bone and along the mid-line. Two characters are recognized for the coracoid and furcula, and both of them distinguish parids from corvids. In the wing, two characters of the humerus and one of the ulna are listed, and five characters are identified in the pelvis, although two of these latter appear to be redundant in defining parids osteologically. In all, of the total of 55 characters, no fewer than 39 distinguish, or largely distinguish, parids from corvids, and in all these respects *Pseudopodoces* is a parid.

Many, perhaps as many as half, of the distinctive osteological features of parids relate to the bill, and it may therefore be appropriate that much of the ecomorphological research that has been undertaken on the Paridae has focused on variation in the bill, both among and within species. Moreover, at least one subspecies, the race *newtoni* of the Great Tit, has been defined purely on the characteristics of the bill. Within species, the size and shape of the bill tend to vary, in relative terms, more than does any

other size character, such as wing or tarsus length, but this tendency itself varies among species. This is largely because some species, or some populations, are strongly sexually dimorphic in bill size and shape, whereas others are not, and the degree to which this is so appears to depend on the relative social dominance of the species. For example, in a British woodland parid community consisting of the Great Tit, Common Blue Tit, Marsh Tit and Coal Tit, in which the species could be ranked in this order in terms both of overall body size and of social dominance, the relative variation in the bill was also ranked in this, descending sequence, because this Great Tit population exhibited strong sexual dimorphism in the bill, while the Coal Tits showed little or none other than that expected from the general dimorphism in body size, which was similar for all four species. The Common Blue and Marsh Tits were intermediate in sexual dimorphism of the bill. The mechanism proposed to account for this suggests that sexual dimorphism evolves in response to intraspecific competition, which is strongest in the socially dominant Great Tit. It is weakest in the small, subordinate Coal Tit, for which interspecific competition prevails. Supporting evidence for this idea came from a study in Ireland, where three of these species occurred in more or less discrete habitats, and the fourth, the Marsh Tit, was absent. Here, Coal Tits experienced only intraspecific competition, and were significantly more sexually dimorphic in the bill than were those in the British wood. The phenotypic plasticity of bill form in the Great Tit, with, for example, sex-specific seasonal change tracking changes in the intensity of social interaction with changing food availability through the year, calls into question the degree to which the bill's morphology can be regarded as strictly under genetic control, rather than being honed for a purpose by the bird's activities, either deliberately, through bill-wiping, or otherwise.

Variation in the bill need not reflect variation in the underlying skeletal elements, since the rhamphotheca, the horny covering of the bill, consisting of keratin, is continuously growing. For the Great Tit, it has been shown that, while the size of the skeletal elements varies with that of the general body size, the size of the rhamphotheca is independent of this. Indeed, it may change seasonally, as it tracks the individual's seasonal change in diet, from insects to seeds and back, and the sexual dimorphism evident in

Tits reside further north than most other passerines. The **Black-capped Chickadee** inhabits Nearctic forests as far north as Newfoundland in the east, and Alaska in the west. Despite its small body size, it does not escape southward in winter, preferring to endure freezing conditions. It is seen here perching in low branches encased with ice! It often favours native forests such as those dominated by birch (*Betula*) or alder (*Alnus*), or the pinyon-juniper (*Pinus-Juniperus*) forests in the Rocky Mountains. Like many north temperate species it occurs at higher elevations in the south of its range, reaching 3200 m in New Mexico.

[*Poecile atricapillus atricapillus*, Montebello, Canada. Photo: Roland Seitre]

this species reflects sex differences in foraging specialization. Furthermore, as the bill size of the Great Tit also determines the size of prey that can be taken during the breeding season, sexual dimorphism may act to reduce competition between members of a breeding pair. The extent to which this is so depends on the degree of competition experienced by the pair-members, and this, in turn, depends on the population density and food availability. Hence, the effect varies among populations, habitats and years.

The form of the bill is one of the most distinctive characteristics of parid genera, being stoutest in *Cyanistes* and some *Baeolophus*, generally intermediate in *Poecile* and *Parus*, and finest in *Periparus* and *Lophophanes*. *Pseudopodoces*, with its long, curved bill, is an extreme case. The bill tends to be finest among species of coniferous forest, such as *Periparus* and *Lophophanes* tits, which pick fine insects from among the conifer needles, and stouter among species that prefer broadleaf deciduous forest, which include most other genera. This bill difference has been described also for populations of Great Tits inhabiting coniferous or broadleaf forests, which tended to have, respectively, a finer bill or a stouter one. Finer bills are clearly related to a more insectivorous diet, and stouter bills to a more seed-based and nut-based diet, so that the Great Tit's dietary shift, from insects in summer to seeds in winter, is paralleled by a shift to a stouter bill in the winter months. Related to this is the tendency for stouter-billed individuals or species to forage more on or near the ground, and for finer-billed individuals or species to be more arboreal, although there are clear exceptions to this, as illustrated by the Common Blue Tit, which is highly arboreal. Hence, it is apparent that both interspecific and intraspecific variation in form correspond strongly to differences in ecology, such as habitat preference, and this is discussed in the following section.

## Habitat

The diversity of habitats in which parids occur reflects both the huge geographical area over which the family is found and the behavioural adaptability of several of the species. Generally ex-

cluding hot, cold or ice deserts, tits and chickadees can be encountered in most of the vegetated terrestrial biomes of the zoogeographical regions in which they occur. Within these biomes, they are found in most habitats, including wetlands to some extent, but many have specific adaptations, for example of the bill (see Morphological Aspects), or requirements, such as for soft dead wood for nest-hole excavation (see Breeding), that predispose them to certain species-specific, optimal habitats. The population density is typically more stable over the years within optimal habitat than it is in suboptimal habitat; this is because, in accordance with the "Ideal-free Distribution" theory, birds "fill up" the better habitat first, individuals arriving subsequently being forced into poorer habitats. Another characteristic that contributes to habitat preference is the rate of song degradation with distance from the singer, which differs from one habitat to another, as has been demonstrated with, for example, the Black-capped Chickadee, the Great Tit and the Common Blue Tit.

Naturally, in consideration of all these factors, a species shows a preference for its optimal habitat. Indeed, species associated with coniferous woodland, such as the Coal Tit, even prefer to perch on a pine (*Pinus*) twig rather than on oak (*Quercus*) if given a free choice. Significant differences in the degree of habitat specialization are nevertheless evident among species, and this is reflected in their geographical ranges. Hence, while a few parids, such as the Great Tit in the Palearctic and the Black-capped Chickadee in the Nearctic, occur in a broad range of habitats, being found in a variety of woodland types, as well as scrub, parks and gardens, in both urban and rural situations, most members of the family are more restricted in their choice, as typified by, for example, many of the African *Parus* species and the Carolina Chickadee. Nevertheless, even the least habitat-specialized species have an optimal habitat in which they achieve their greatest breeding density and breeding success, and in which populations are more stable than they are in suboptimal habitat. For the Great Tit in Britain, for example, oak woodland represents this optimal habitat.

Across a species' range, the extent to which it can express its habitat preference is naturally limited by the availability of either

The **Varied Tit** occurs in the Far East, where it occupies a geographically variable spectrum of habitat types. In mainland China it tends to inhabit open deciduous and mixed forests; on Taiwan it prefers lowland conifer forests; and in Japan it is usually found in mature deciduous, mixed and evergreen broadleaf forests. Despite harsh winters in the northern portion of its range, and regardless of habitat choice, it is essentially resident. Although this species is relatively large, it bears a strong resemblance to some *Pariparus*. However, recent DNA evidence, along with its habits of food-hoarding and nest-hole excavation, clearly indicate that it is an aberrant *Poecile*.

the optimal habitat or surrogates. As an example, the Common Blue Tit is typically an inhabitant of oak woodland, and it shuns large stands of conifers. In north-west Europe, this is reflected in its reaching its highest densities, often more than one pair per hectare, in pedunculate oak (*Quercus robur*) woods. In north Africa, this tit is characteristic of cork oak (*Quercus suber*) but, when it moves to higher altitude, such as in the Atlas Mountains, it is found in pine and cedar (*Cedrus*) woodland, as well as in montane oak woodland. This species frequents similar habitats at high elevations in the eastern Mediterranean and the Middle East.

The Paridae featured prominently in D. Lack's classic 1971 work *Ecological Isolation in Birds*, in which the author observed that two congeneric species rarely occupied the same habitat, and that, if they did, they would tend to occupy significantly different ecological niches within it. Although the classification of the tits at that time in a single genus (see Systematics) presented some problems for this argument, Lack realized that, in this family, the level of subgenus appeared to be more appropriate. It seems, therefore, that his observations on habitat occupancy pre-empted the promotion of subgenera to genera that was to occur some 30 years later. As a general principle, Lack observed that two congeners rarely occupied the same location without some shift of niche space occurring, a fact already remarked upon with regard to the sympatric African *Parus* species (see Systematics). Hence, for example, the seven parid species found in western Europe now represent six different genera. More recent research on habitat occupancy by tits has attempted to identify specific habitat characteristics that affect the fitness of the birds, such as canopy height in the case of the Marsh Tit and oak-tree density and soil type in the case of the Great Tit.

As habitat preference is dictated by the close integration of a species' ecology, behaviour and morphology, it should be expected that, despite the breadth of habitats occupied by parids, there are some general patterns broadly associated with the genera. The suggestion that the Paridae possibly originated in the Himalayas (see Systematics) would indicate that they are typically birds of high-altitude, evergreen or montane deciduous forest and associated habitats, although it should be noted that bird species asso-

ciated with high elevations when at low latitudes are often found at lower elevations when at higher latitudes. While it would be naive to suggest that this represented the "primitive" condition for habitat preference in the Paridae, the Yellow-browed Tit, which, together with the Sultan Tit, was considered by Gill and colleagues to be basal to the parid evolutionary tree (see Systematics), certainly occupies such a range of habitats. The Yellow-browed Tit lives at 2000–4000 m and is a bird of temperate montane and submontane forests, mostly of oak and or rhododendron (*Rhododendron*), but then moving through mixed forests into conifer forest at higher altitudes, and into scrubby habitats, especially of willow (*Salix*), along the tree-line. Although typically below 2000 m, the Sultan Tit is likewise a denizen of submontane and lower-altitude montane deciduous, mixed deciduous and evergreen forests, while the Ground Tit, the extreme high-altitude representative of the other monotypic parid genus, occurs on treeless steppes at 3100–5500 m on the Tibetan plateau. Together, these three species cover most of the broad habitat types occupied by the family.

The habitat theme of high-altitude willow thicket occupied by the Yellow-browed Tit along the Himalayan tree-line is picked up strongly in the habitat descriptions of the genus *Poecile*. More broadly, *Poecile* tits and chickadees are species of damp woodland or scrub, or riverine woodland or carr; these are the typical habitats of, for example, the Marsh, Willow and Siberian Tits, the Boreal, Carolina, Chestnut-backed and Black-capped Chickadees, and the White-browed and Rusty-breasted Tits. Other high-altitude features of the *Poecile* habitat theme that are frequently represented are birch (*Betula*) and alder (*Alnus*) in addition to willow, which are characteristic of the habitats of most of the nine species just listed, and an admixture or pure stands of conifers, some component of which occurs in the habitat preference of all *Poecile* species, including those in drier, more southerly latitudes, such as the Mexican Chickadee and the Sombre Tit. A further important feature for many *Poecile* species is the presence of dead trees, stumps or "snags" in which to nest, and this may impose a significant limitation on the occurrence and/or population dynamics of these species. For spe-

Most tits gather, at least occasionally, in either mixed-species or single-species flocks. Flocks often form in cold weather because foraging as a group improves both foraging efficiency and predator detection, and in many regions parids are nuclear species of these flocks. On other occasions flocks form during mass movements. Parids are amongst the most sedentary of birds, but some species, including the **Willow Tit**, undergo periodic population eruptions. These individuals may be taking part in such a movement after a failure of the Scandinavian beech mast or pine seed crops.

[*Poecile montanus borealis*,

cies such as the Willow Tit and the Carolina Chickadee, which excavate their own nest-holes (see Breeding), the presence of soft, damp dead wood probably facilitates nesting. Nest-sites in dead wood, however, are described also for several species which do not excavate their own nest-chamber, such as the Siberian Tit. Interestingly, the latter's nearest relative, the very similar Boreal Chickadee, does excavate.

Nowhere is the importance of conifers as a habitat theme as prominent as it is for the seven members of the genus *Periparus*. Three of these, the Black-breasted, Spot-winged and Coal Tits, are true conifer specialists, two others, the Yellow-bellied and Elegant Tits, favour evergreen and mixed forests, which include conifers, and one, the Palawan Tit, is a bird of diverse forest types including secondary forest, edges of swamps and submontane regions. Only one, the Rufous-vented Tit, is an inhabitant chiefly of broadleaf, deciduous forests, especially of oak, although even this species can occur in mixed forest with a high proportion of conifers in the stand. In this, it contrasts sharply with the larger Black-breasted Tit, with which it forms a superspecies. Both occur at very high altitude, around 2000–4000 m, and, although their ranges overlap, the Rufous-vented Tit has a more easterly distribution. Also characteristic of *Periparus* is the preference for full-height mature forest: these are perhaps the most truly forest-loving tits. As was noted before for the Great Tit, *Periparus* species likewise may occur in other habitats. Coal Tits, for example, especially in years of high population density, breed at a low density of about one pair per 10 ha in oak woodland, although often in association with a single mature conifer, but their breeding success is typically poorer in broadleaf habitats; in conifer forest, *Periparus* tits often breed at high density.

Consistent with their general preference for conifer forest is the fact that the *Periparus* species are the most uniformly fine-billed of the parids. The two *Lophophanes* species, the European Crested and Grey-crested Tits, are similarly fine-billed and exhibit some preference for conifer forest, although this differs among populations. Northern populations of the European Crested Tit are conifer specialists. In Britain, for example, this species is restricted to the Scots pine (*Pinus sylvestris*) of the Caledonian

forest of Scotland. In central and southern Europe, however, it occurs in a wider range of habitats, including broadleaf woodland. Farther south also, it tends to live at higher altitudes. The Grey-crested Tit is a bird of very high-altitude forests, but it occurs in a wide range of broadleaf, mixed and conifer forests. Unlike the fine-billed *Periparus* species, which do not excavate their own nest-chambers, the two *Lophophanes* tits do excavate, and the need for dead wood imposed by this may place a constraint on the type of habitat most suitable for them.

As already noted, the *Baeolophus* titmice share a number of characteristics with the preceding genera, which may have bearing on their habitat preferences. Lack noted that the geographical distributions of three of the *Baeolophus* species, which constitute the "tufted titmouse" superspecies, formed a mosaic pattern of more or less non-overlapping ranges. These three were the Tufted Titmouse in the eastern USA, the Black-crested Titmouse in Texas and northern Mexico, and the Plain Titmouse in the western USA. The last-mentioned was subsequently split into two species, the Oak Titmouse and the Juniper Titmouse, on genetic, morphological, geographical and ecological, largely habitat, grounds. Whereas the Oak Titmouse is found primarily in oak or oak-pine woodlands of the Pacific slope, the Juniper Titmouse inhabits juniper (*Juniperus*) and piñon-juniper woodlands of the inter-mountain region. As Lack suggested, however, the members of this superspecies are chiefly birds of broadleaf woods. The habitat of the remaining member of the genus, the Bridled Titmouse, is similar, but, where this species does overlap in range with any of the three tufted titmice, it occupies a distinct foraging niche because of its much smaller size. As with the other seed-hoarding parids, riparian habitats may feature prominently within the ranges of *Baeolophus*.

*Parus* is a rather disparate genus, containing some important superspecies groupings. As such, *Parus* species occur in practically every Old World habitat in which the family can be found. In Africa south of the Sahara, tits are typically birds of savanna, from open park savannas to wooded savannas, including various kinds of acacia (*Acacia*) savanna and woodland, thornbush, dry mopane (*Colophospermum mopane*) thicket, and miombo wood-

Parids are energetic and boisterous. With their constant movement, cheerful call notes, and conspicuous antics, they are amongst the most popular of garden birds.

As it happens, many of their antics are not so much playful, as competitive. There are complex dominance hierarchies between and within parid species, and these come to the fore when conditions are harsh and food supply limited. At such times contests over food are commonplace, but usually settled with a minimum of fuss via brief agonistic displays. Typically, a dominant bird will make a forward lunge, with wings outstretched and bill open, and a subordinate bird will concede defeat by flying to a nearby perch. This system avoids escalated battles and saves much time and energy.

The **Great Tit** is dominant over other tits in Europe, and uses the same type of display to dislodge several other passerine species—in this case a female **Common Chaffinch** (*Fringilla coelebs*).

FLPA]

land. As noted already, members of a superspecies are ecologically isolated largely because of their non-overlapping geographical ranges. Specific cases of habitat avoidance, apparently through intrageneric competitive exclusion, are also recorded. For example, the Rufous-bellied Tit, which occurs in mature miombo woodland and savanna habitats with the Miombo Tit, though occupying a slightly different niche, appears to be avoided by Southern Black Tits, which are found in miombo woodland only where the Rufous-bellied Tit is absent. A few African species extend into the savanna edge of the rainforest zone, into riparian thicket, woodland or forest, or into gallery forest: examples are the White-shouldered Black Tit in north-central Africa; the White-winged Black Tit in south-central Africa; the White-bellied and Red-throated Tits, generally not together, in east-central Africa; and the Dusky Tit in central Africa. The presence of water is important also to the Somali Tit, and the Ashy and Grey Tits of southern Africa tend to be associated with dry river courses. A specific association with montane forest habitats including juniper woods, dry *Podocarpus* forest, montane evergreen forest, highland *Hagenia* forest, primary and secondary evergreen forests and tree-heath is exhibited also by the White-shouldered Black, White-winged Black, White-bellied, White-backed Black and Stripe-breasted Tits. As with other *Parus* species, none of these excavates its own nest-hole. This, together with the facts that most of these species occur at very low densities, and that some are known to be co-operative breeders and to reuse nest-holes in successive years, suggests that the availability of nest-sites may be limiting to the populations of these species, especially in the dry thornbush habitats.

The remaining eight *Parus* species collectively occupy practically every vegetated habitat of the Palearctic and Oriental Regions, and illustrate well the principles of niche separation within or between habitats or ranges. The Great Tit, the single most varied and widespread parid in the world, occurs in every kind of forest, scrub or bushy habitat, and in both primary and secondary forest, and it is the only member of the family specifically associated with mangroves in a part of its range. Generally, it thrives best in broadleaf forest, although it tends to prefer conifer forest in areas where the Green-backed Tit is present. The Great Tit is, however, largely a lowland species, rarely occurring above 2000 m. Habitat use by the very closely related Turkestan Tit is similar, but the ranges of the two species overlap little; where they

do, the species may interbreed, and they were formerly considered to be conspecific. The similar, but smaller, Green-backed Tit avoids competition with the Great Tit generally by living at higher altitude, up to about 4000 m. South of the Himalayas, the White-naped Tit now occurs in dry acacia thorn-scrub, recalling the major habitats of the African *Parus*, although formerly it was found in south-west India mostly in moist deciduous forest. The Black-lored and Yellow-cheeked Tits, a sibling pair the ranges of which barely overlap, occupy a wide range of forest habitats, including submontane and montane, temperate and subtropical, deciduous or mixed, forests, but generally with oak, pine and rhododendron present.

This survey of parid habitats has hitherto focused on breeding habitat. Outside the breeding season, many of the species occur in a wider range of habitats. This may be because of a shift in diet from invertebrates in summer to seeds in winter, which dictates that a habitat shift is necessary; one example of this concerns the Great Tit, which in Europe forages extensively in beech (*Fagus sylvaticus*) for seeds in the winter months, but for which beech woods represent poor breeding habitat. Alternatively, it may be because of population pressure caused by the increase in bird density after breeding, which, through competition, pushes subordinate individuals into suboptimal secondary habitat, generally scrubby rather than wooded. Such a situation is apparent for many species, among others the Marsh Tit, the Black-capped Chickadee and the Yellow-bellied Tit, but the real extent and importance of this kind of dispersal are shown by the occurrence of parids in anthropogenic habitats such as cultivation, orchards, olive groves, parks and gardens. Of the 56 members of the family, no fewer than 30 have been recorded in anthropogenic habitats, including members of all genera except *Pseudopodoces*, in all zoogeographical regions where parids occur. Of these 30, as many as 23, or 77%, have been recorded in parks and/or gardens, where many of them come for food purposefully provided by humans. The other seven species may occur in such places as orchards or olive groves, or at the edge of or on cultivated land, at some time during the year; eleven of the 30 are recorded only in parks or gardens, and a further twelve species are associated with both garden-type and cultivation-type habitats. In most cases, these species either do not breed in anthropogenic habitats, or do so at lower densities and with poorer success than is the case in their primary habitats.

The **Ground Tit** is often found in pairs or small groups. It skims low to the ground on fluttering wingbeats, bobs on alighting, and proceeds with long hops across open ground. Individuals frequently flick the wings and tail, and display with wings held high, as depicted here. These habits are strikingly different from those of arboreal tits, and more similar to a variety of other ground-dwelling groups, such as wheatears (*Oenanthe*) or Cinclodes (*Cinclodes*), emphasizing the fact that signalling displays are shaped by ecology as well as phylogeny.

[*Pseudopodoces humilis*, Litang, Sichuan, China. Photo: Christian Artuso]

Comfort behaviour in parids involves a range of typical strategies. All members of the family commonly preen, often shortly after bathing. Preening is undertaken using the bill, with frequent applications of oil from large uropygial gland. It is also usually interspersed with bouts of wing-stretching, as demonstrated by this juvenile **Rusty-breasted Tit**, and head-scratching, which can be achieved either directly or indirectly (over the wing).

The significance of gardens and other artificial habitats is highlighted by studies of habitat fragmentation, for which parids have been critically important because of their ubiquity and relative ease of study. Forest fragmentation has a number of major effects on the ecology of tits: it isolates parts of otherwise continuous populations, potentially reducing gene flow between them; it may increase the energy costs incurred by the birds in crossing areas of unsuitable habitat; it can increase the birds' exposure to predation risk; and it may reduce breeding success and individual condition because prey densities have been found to be lower in small woodland fragments compared with continuous blocks of woodland. For example, a British study found that the breeding performance of Great Tits and Common Blue Tits declined with decreasing size of woodland area. For the latter species, this was because pairs in smaller woods bred later, when food was less abundant. In addition to this effect, Great Tits reared lighter young in smaller woods. The effect of woodland size on laying date was substantial, accounting for 25% of the variation in laying date of Great Tits and 33% in the case of Common Blue Tits. In another British study, the breeding success of Great Tits was reported as being poorer in gardens than in scrub, which itself was poorer than in a large woodland block. In a Belgian study, it was found that local recruitment of Great and Common Blue Tits to the breeding population was greater in large woodland plots than in small ones. Local recruitment was higher in forest fragments than in similar-sized plots within continuous forest, suggesting that fragmentation reduced the movement of birds among local populations; it appeared not, however, to be related to the degree of isolation of individual fragments. In a different Belgian study, European Crested Tits hatched in woodland fragments were found to have a lower chance of settling in their preferred habitat, because they tended to disperse later than did young from larger woodlands. Other studies suggest that forest fragments do not always provide poorer feeding conditions than those in larger patches. A further effect of "hard" edges of forest fragments is that, outside the breeding season, tit flocks may tend to follow the edges, rather than foraging within the forest interior. This has been observed for chickadee flocks in Canada, and suggested a reluctance on the part of the birds to move between woodlots. Whether this tendency increased the risk of predation is not known.

The importance of the Paridae in research on habitat fragmentation is further indicated by two recent studies of Great Tit populations, one in Britain and the other in the Netherlands. Both in Wytham Woods, a continuous block of woodland in southern England, and on the Dutch island of Vlieland, it was found that variation in habitat quality within one and the same site can restrict the movement of individuals, and thus gene flow, sufficiently to cause differential evolution in different parts of the same population.

### General Habits

The relative ubiquity of the Paridae in the Northern Hemisphere, coupled with their naturally inquisitive nature and willingness to associate with humans, results in their general habits seeming very familiar, even commonplace, to most people there. In general, parids are highly active birds, busily inspecting foliage and branches in search of food. They are generally territorial when breeding, and they are social when not breeding, at which time they form single-species groups and/or join other species, of both Paridae and others, to form mixed-species flocks. They declare or advertise their territories by song, and they defend them by a hierarchy of escalating facets of behaviour, ranging from song and display, involving specific plumage badges and advertising postures, to chasing and fighting. All parids are hole-nesters, a fact which distinguishes them from some of their closest relatives, such as the penduline tits and the long-tailed tits. Parids, especially paired adults, may form the nucleus of non-breeding flocks, but often that is provided by members of another family, such as the Long-tailed Tit (*Aegithalos caedatus*) in Europe. The composition of flocks varies through the year, in terms both of the species joining the flocks and of the very individuals within a species that join. It is not unusual, for example, for adult male Great Tits to continue to sing on their territories through the winter, while also spending time each day in foraging with a flock up to 1 km away.

For a number of Holarctic parid species, the behavioural aspect of flocking has been studied in detail. The advantages of flocking are two-fold: predator detection on the one hand and, on

Tits, like most woodland passerines, are fond of bathing. They prefer to undertake this activity on the secluded, gently sloping shores of ponds or streams. After landing belly-deep in shallow water, they briefly duck the chest under the surface. Then follows a period of variable length during which they flutter their wings energetically, usually alternating from side to side, as demonstrated by this **Carolina Chickadee**. This species is common in the south-east USA, intergrading in a narrow hybrid zone with its close relative the Black-capped Chickadee (*Poecile atricapillus*), which replaces it to the west and north.

[*Poecile carolinensis* extimus,  
Hamilton County,  
Ohio, USA.

Maslowski Productions]

the other, foraging enhancement. Put simply, a group of birds is more likely to detect a predator than is a single individual, and individuals learn the whereabouts of the best places at which to seek food by watching other flock-members. A trade-off or tension between these two functions is, however, evident. This is because, while there is an advantage in foraging with conspecifics in terms of learning where to forage, there is more competition for that food with conspecifics occupying the same niches than when foraging with members of other species, which can also detect predators. Mixed-species flocks, however, can function well in terms of mutual predator avoidance only if every individual in the flock "speaks the same language". In this regard, it is noteworthy how similar are the alarm calls of parids even across vast distances. This is demonstrated by comparing, for example, the social calls of the Bridled Titmouse in the south USA with those of the Common Blue Tit in Europe (see Voice).

With much of the annual cycle, the precise details, and especially the timing, of events vary with climatic conditions, but a general pattern of the parid year is as follows. After a variable period of territory establishment and defence, breeding takes place in spring, typically during April–June in north temperate regions and January–June in more southerly areas of the Northern Hemisphere, and in August–December in the Southern Hemisphere. Breeding is followed by the formation of family flocks with dependent young, which coalesce into monospecific non-family flocks and/or mixed-species flocks. The moult occurs after breeding. Winter flocks break up in the early spring, when males increasingly establish breeding territories. Flocking results in copious opportunities for intraspecific and interspecific agonistic interaction, especially in relation to social dominance and access to food. This has important consequences for the tits' management of energy reserves, their survival prospects and so on. It has probably also contributed to the evolution of parid intelligence, the tits being, together with two other highly social avian groups, the parrots (Psittacidae) and the corvids, among the most intelligent of all birds (see Food and Feeding).

While the outline given above is broadly applicable to all parids, there are important differences of detail among species. Ultimately, these differences appear to be driven by a suite of correlated behavioural and ecological factors, including social dominance, population density, and mortality rate or risk. Hence,

one can perceive a continuum of variation from "pair-territorial" species that remain paired for life and remain on their territory throughout the year, these including several *Poecile* species, the European Crested Tit and the Oak Titmouse, through to "group-territorial" species, in which the stable pair, having bred, forms a nucleus, sometimes with another adult pair, for a small stable flock, typically with one or a few juvenile pairs. This latter form of social organization, which appears to be by far the most common in the Paridae, again includes many *Poecile* species, such as Varied, Willow and Marsh Tits and Black-capped and Mountain Chickadees, and also the European Crested Tit, the Bridled Titmouse and the Southern Black Tit. The stable flock may defend

Whether they are foraging in mixed-species flocks in midwinter, or announcing territory ownership in spring, tits are noisy birds. Many species give incessant contact calls when foraging, and most have distinctively metallic or nasal songs, heavy on rhythm and light on melody. The **Chestnut-backed Chickadee** is no exception, having a song made up of repetitions of the call notes, some sweet and some churring. Being oscines, parids develop their songs through an imprinting-like process which produces repertoires, dialects and individual variation.

[*Poecile rufescens* rufescens,  
Portland, Oregon, USA.  
Photo: Arthur Morris/  
Birds as Art]

The typical parid foraging niche is that of a generalist. All members of the family eat invertebrates, but many, especially those living at high altitudes or latitudes, switch seasonally to a diet of seeds and fruit. The smaller species, such as the **Common Blue Tit**, are well known for their technique of hanging by one or both legs, upside-down, to inspect foliage, branches or, as in this case, pine cones for food. Whether this individual is currently searching for nuts or insects is difficult to say, as both items are taken opportunistically.

[*Cyanistes caeruleus*

Eriksen]

its collective home range against members of other such flocks, but the pairs within the group do not defend territory within that range. At the farther end of the continuum are the true flocking species, including the Great Tit, the Common Blue Tit and the Coal Tit, breeding partners of which may remain paired through the winter and form a nucleus for a flock, but the composition of that flock varies over time. It can be more or less constant and consist of a few juveniles associating with the adult pair, in which case this "basic flock" may appear similar to the organization of the group-territorial species; alternatively, it can be a wholly random assortment of other conspecifics, their membership of one or another flock changing from day to day, and the flocks' home ranges may overlap.

It will be apparent that this "gradient" of socialization, which is effectively a continuum of social cohesion in terms of group membership, varies across genera. While this is broadly true, one should, however, note that different populations of a given species fall into more than one group, as illustrated by, for example, the Varied, Willow and Marsh Tits and the European Crested Tit, indicating that social organization responds to local ecological conditions, rather than to specific genetic tendencies. The pattern should therefore be perceived as being far more flexible; it would be wrong to think of this variation simply as a taxonomic distinction. This broad continuum, however, parallels a number of other trends. The pair-territorial and group-territorial species tend to be more socially subdominant when in mixed-species flocks, especially when with such flocking species as *Parus* or *Cyanistes* tits; they tend also to scatter-hoard food such as seeds, whereas flocking species tend not to, although the Coal Tit is an exception among the latter. Compared with flocking species, pair-territorial and group-territorial species tend to occupy larger territories and to breed at lower density, but to have more stable populations over time: this is especially true of chickadee populations, which have been reported as being highly stable over several decades. Perhaps related to this is the fact that they tend to experience lower annual adult mortality, typically 30–50%, compared with 50–70% for flocking species.

Pair-territorial and group-territorial species are more likely to excavate their own nest-hole, and may also be co-operative breeders. Here, perhaps, is the most significant departure from a strict taxonomic classification and towards an ecological one,

because many of the African *Parus* tits are, or are believed to be, co-operatively breeding pair-territorial or group-territorial species. Relating to these gradients also is the duration of juvenile dependency, or the period until juveniles leave the natal territory, which is longest among group-territorial species. In the case of the Varied Tit, a species which may also be a facultative co-operative breeder, it may be as long as three months.

A distinction should be made between the various kinds of flocks described herein and the aggregation of birds at a temporarily available food source. The composition of an aggregation can differ totally from that observed in stable or basic flocks. For example, while the number of parid conspecifics in a true flock would rarely exceed ten and would have a more or less predictable age structure, aggregations of up to 100, mostly first-year, Great Tits feeding on beech mast are not uncommon in England, and all-adult flocks of 40 Great Tits have been trapped while feeding on yew (*Taxus baccata*) seeds in Killybegny, in the Republic of Ireland. Within these Great Tit aggregations, there is typically a high frequency of interactions in which, for example, an individual with a seed is supplanted by another. In these situations, as in most parid flocks that have been studied, males outrank females and, within sexes, adults outrank juveniles or first-year individuals; this may differ in group-territorial species, in which females of the alpha pair outrank all except the alpha male. Hence, it has been noted that, as the beech crop becomes depleted through the winter, it is the most subordinate individuals that are the first to leave; the last to depart are adult males.

Another feature running alongside the gradient of social organization is that of plumage contrast, or, more specifically, of "badging". Badges of dominance, or fitness-coloration, include bills, eyebrows and wingbars. Whereas the most pair-territorial parid, the Coal Tit, has the least developed of these, in terms of badges of dominance, the most extreme of the flocking species, namely the Great Tit and the Common Blue Tit, are positively "badging" with badges indicating age, sex, nutritional status, and often, The correlation between plumage badges and agonistic interaction is likely to be a real functional one. It has been noted that, within pair-territorial and group-territorial species, the frequency and intensity of intraspecific agonistic interactions are much less than those within flocking species. In the latter, flocking behaviour itself is weather-dependent, in

Although food-caching has not been reported for the **Yellow-bellied Tit**, it is known in several other members of the *Periparus* clade. While this individual may be foraging on the ground, a not unusual event in some parids, it is perhaps more likely that it is carrying a seed to a cache, or indeed retrieving it. The main food-caching tits are in *Periparus* and *Poecile*, some of which cache hundreds of thousands of items per year, and are known to retrieve up to 95% of their caches. The recall necessary to achieve this feat is quite astounding, and presumably contributes to the evolution of parid intelligence.

[*Periparus venustulus*, Lam Tsuen, Hong Kong. Photo: John & Jemi Holmes]

that members of non-stable flocks are more likely to join flocks when conditions are hard. This has been described also for the Varied Tit, which tends to join mixed-species flocks in tougher weather, or when not fed by humans, though when conditions are milder, or food is provided, Varied Tits form only single-species groups. This is because the increased need to find food reduces the time available for vigilance, and the only way in which to reduce individual vigilance safely is to share the task in a flock. Variability in flocking behaviour resulting from day-to-day changes in ambient temperature means, however, that the individuals comprising a flock on one day may not be the same as those present on another day. One result is that, unlike the situation with the pair-territorial or group-territorial species, in which individuals "know" each other and clear dominance hierarchies are well established, such hierarchies cannot be so clearly based on previous experience in flocking species. If birds do not recognize each other as individuals, the generalized conventions of social dominance, based on such factors as sex and age, must be indicated by some other means, such as plumage. Nevertheless, dominance ranks among many Great Tits have been shown to be stable throughout a winter, with high-, middle- and low-ranking individuals constantly so placed.

Whether through appearance, convention or trial, tit species within mixed parid flocks also have a more or less stable rank in the flock. In Europe, the typical situation is that Great Tits outrank Common Blue Tits, which outrank Marsh Tits, which are dominant over Willow Tits, which usually outrank Coal Tits. European Crested Tits, when present, slot into this sequence after Common Blue Tits, and the presence of Siberian Tits influences the hoarding sites used by Willow Tits. Similarly, in North America, the Tufted Titmouse, the largest parid in the Nearctic, is dominant over all other species at birdfeeders. The most demonstrative way in which these rankings are manifested is in shifts in a species' foraging location in the presence of a higher-ranking species (see Food and Feeding).

It is interesting to note here how relatively lacking in badges are the African black tits, namely the Southern Black, Carp's Black, White-winged Black and White-shouldered Black Tits, the social organization of which appears more similar to that of most *Poecile* and *Baeolophus* species than is that of the flocking

*Parus* species of the Palearctic and Oriental Regions. Unfortunately, the social organization of most of the African grey-tit group, consisting of the Somali, Miombo, Ashy and Grey Tits, is largely unknown. It has been argued that co-operative breeding by the tits of southern Africa has evolved because a significant anti-predator advantage is obtained from group-living in the savanna in any season. Coupled with the low densities of these species, with territories of up to 30 ha for a single pair, presumably because of a paucity of nest-sites, and a low reproductive rate, with clutches typically of fewer than five eggs, this means that it is beneficial for individuals that cannot find a mate of their own to remain in a group, helping to raise young of the alpha pair, than to wander as "floaters" in the hope of finding an unpaired conspecific. A similar reasoning may underlie the group-territoriality and co-operative breeding practised by some *Baeolophus* titmice.

Supporting the suggestion that, among the Paridae, plumage badges and elaboration have co-evolved as a package with social organization is the relative lack of contrast in the plumage of the Azure Tit. This species' life in the boreal forests of Siberia imposes on it a low breeding density and probably also a necessity to maintain stable flocks, as this is one of very few parid species known regularly to roost communally, another such being the White-bellied Tit of the Afrotropics. When not breeding, the Azure Tit is typically seen in pairs or small flocks, suggesting that its social organization may be more like that of a *Poecile* tit than that of its nearest congener. In the winter months, most parid species roost singly in holes in trees or in rodent burrows in the ground; in summer, they often roost on a branch near the tree trunk. Most members of the family living in the boreal zone belong to the genus *Poecile*. These northern tits, in addition to hole-roosting, become hypothermic, reducing their body temperatures by 5–12°C and, thus, lowering also their metabolic rate and energy consumption. This has been recorded for at least four *Poecile* species, these being the Willow and Siberian Tits and the Carolina and Black-capped Chickadees. Perhaps *Cyanistes* species cannot do this.

Parids undertake various types of maintenance and comfort behaviour. They use the bill when preening, for which purpose they possess a large uropygial gland. They also carry out both

A **Tufted Titmouse** uses its innate agility to extract food items from difficult locations. Once it has removed a sunflower seed from the head of a sunflower, it uses its bill to manipulate the husk, and break out the kernel. The same technique is more or less repeated throughout the family. Titmouse bills are small, but very powerful, and they are capable of giving a painful nip. The same is true of most parids, although conifer specialists, such as *Periparus*, tend to have much finer bills.

direct and indirect scratching. Some members of the family have been observed to indulge in passive anting, in which they squat and allow ants to run over them.

## Voice

Being highly social species, the tits and chickadees are among the most vocal of passerines, frequently issuing quiet contact calls while foraging, even when apparently solitary, but also giving a range of louder calls, which are more or less context-dependent. Indeed, so rarely are parids silent that, when they are, that silence itself is context-dependent, being indicative of, for example, a male avoiding detection by a territory-holder, or of the presence of a predator. Before DNA analysis offered some resolution to the systematics of the Paridae (see Systematics), attempts were made to reach a natural classification on the basis of vocalizations. That this might be possible was suggested especially by the commonality of calls, such as, in particular, the “chick-a-dee-dee”-type calls and “fee-bay” or “see-bay” types of song produced by most *Poecile* species, especially in the Nearctic and the western Palearctic, which in the former region give them their vernacular name of “chickadee”. Closer examination, however, even simply of the voice descriptions presented in field guides, indicates that calls and songs of the Paridae cross generic boundaries in the same way as do such plumage features as wingbars (see Morphological Aspects). Hence, the familiar “teacher-teacher” song of the Great Tit, the Turkestan Tit and other *Parus* species, in both Asia, as typified by the Yellow-checked and Yellow Tits, and Africa, as by the White-winged Black and Stripe-breasted Tits, is produced also by a *Poecile* species, the Sombre Tit, by a *Periparus* species, the Elegant Tit, and by *Cyanistes* species in regions where the Great Tit is absent, as by the Common Blue Tit in north Africa and by the Canary Blue Tit; songs reminiscent of the Great Tit’s are produced by other *Periparus* species, in addition to the Elegant Tit, one example being the “teehuu, teechuu” song of the Coal Tit. Similarly, the explosive “pichou” call usually associated with *Poecile* species, such as the Marsh Tit, has been recorded from the Great Tit, the Elegant Tit and the Common Blue Tit, in the respective genera *Parus*,

*Periparus* and *Cyanistes*, while the nasal “eez-eez-eez”-type calls most typical of *Poecile*, such as the Willow Tit, are sometimes given also by *Parus*, such as the Red-throated and White-bellied Tits in Africa, as well as by the Black-crested Titmouse in the genus *Baeolophus* and by two *Periparus* species, namely the Coal Tit and the Elegant Tit. Even the “chick-a-dee-dee” motif of *Poecile* is recalled in the “tsi-tsi-chay-chay-chay” of the Somali Tit. Moving even farther apart, both geographically and genetically, the “churr” call of the Bridled Titmouse, a *Baeolophus* species, is remarkably similar to that of the Common Blue Tit, though the common ancestor of these two must be very ancient.

The reasons for the failure of vocalizations to parallel phylogeny are similar to those that cause plumage patterns to fail

[*Baeolophus ridgwayi*,  
ridgwayi,  
Arizona, USA.  
Photo: Roland Seitre]

To kill invertebrates or to extract seeds from tough husks, some parids use a technique called “hold-hammering”. This is most common in the stubby-billed genera, such as *Parus*, *Poecile*, *Cyanistes* and *Baeolophus*. Food items are held with the feet (caterpillars or similar prey under one foot, seeds between both feet), and then struck repeatedly with the bill, as demonstrated by this **Juniper Titmouse**. This persistent hammering is powerful enough to crack open a hazelnut (*Corylus avellana*), although it may take 20 minutes.

During hard weather the dietary spectrum of parids widens. Species such as the **Common Blue Tit**, an inveterate hunter of caterpillars during the chick-rearing season, turn to seeds and fruit. These individuals are eating rowan (*Sorbus*) berries in the Finnish winter, but a wide variety of plant species are plundered, including figs (*Ficus*), mistletoe (*Viscum*), and blackberry (*Rubus*). In spring, the Common Blue Tit also forages on sap taken from the bark of trees such as sycamore, maple and walnut, and it is sometimes noted gleaning nectar from flowering trees, including willow, plum and cherry.

[*Cyanistes caeruleus caeruleus*.]

The **Mountain Chickadee** forages actively in the middle to lower levels of trees, searching trunks and branches, gleaning from foliage and needle clusters, and occasionally descending to the ground. This individual has been using its feet to hold an object steady while extracting food items with the bill, a common tactic in the Paridae. In this case the target is leaf buds, a popular food item during the late winter months, along with conifer seeds and berries. This species stores seeds throughout the year, and retrieves them during the winter.

systematically. In other words, while there is a certain evolutionary inertia – and, in cases such as the chickadee alarm calls, this itself is adaptive in permitting interspecific communication in mixed-species flocks – the properties of vocalizations are equally adaptive in that they are optimized for particular habitats. As a result, the vocal patterns throughout the family exhibit interspecific similarity both through common ancestry, or homology, and through convergence, or analogy.

With this in mind, a survey of vocalization is most usefully viewed in terms of the occurrence of specific call motifs, rather than in relation to particular taxonomic groupings such as genera, although the generic characteristics of certain calls, especially of chickadees, should be considered also. Parid calls range from quiet “see-see-see”, “tsi-si-si” or “si-si-si” notes, through soft to harsh “chrrrrr” notes, to more or less explosive (literally, plosive) “pitchoo”-type calls. Call-note repetition, such as “si-si-si”, rather than just “si”, is frequent among the Paridae, and the number of repeated elements may indicate the intensity of expression. For example, the “chic-a-dee-dee” calls of Nearctic *Poecile* species are used as a means of signalling alarm, and field experiments with stuffed predators have demonstrated that the number of “dee” elements increases with the perceived level of threat. Moreover, this is a reliable indicator of threat, or of the true risk, since smaller predators, such as small owls (Strigiformes), that prey on chickadees elicit a stronger response, with more “dee” notes, than do large, fiercer-looking predators that rarely prey on chickadees, such as large owls. Single, quiet, “sip”-type calls appear common to most parids, and are probably used in order to maintain flock cohesion, as contact calls. A prolonged high-pitched “seeeee” is uttered by many bird species, including non-parids, to signify the possible presence of a predator, usually an avian one, the exact position of which is unknown. This avian-predator alarm is adaptive, because its caller is difficult to locate, or it even appears to be ventriloquial. Expanding of the “sip” call in terms of numbers of elements to “see-see-see”, “sip-sip-sip”, “tsee-see-see” or “tsip-see-see-see”, and so on, appears to signify mild alarm in nine species of *Poecile*, five *Periparus* species, both of the *Lophophanes* crested tits, four of the five *Baeolophus* titmice, 16 *Parus* tits, the Common Blue Tit and Azure Tit in *Cyanistes*, and the Yellow-browed Tit in the monotypic genus *Sylviparus*.

A “tsee” or “tsi” note may often prefix more complex motifs, as in the “tsi-tsi-chacha” motif of the Southern Black Tit. Phrases similar to this are given by many other African *Parus*, including, for example, “tsi-tsi-tsi-er-er-er...” by Carp’s Black Tit, “si-chah-chah-chah” by the White-bellied Tit, “tsi-za-za-za-za” by the White-backed Black Tit, “tsitsi-chaa-chaa-chaa-chaa” by the Rufous-bellied Tit, “tsi-tsi-de-de-de-de-de” by the Somali Tit, “sisisisi-cha-cha-cha” by the Ashy Tit and “tsi-cha-cha-cha” by the Grey Tit. Given the necessary presence of a human observer when these calls were recorded, it is likely that they have a similar warning function to the “chick-a-dee-dee” call of *Poecile*. An extension of these polysyllabic calls, as it consists of a number of rapidly repeated elements, is the more or less scolding churring call, often, as with the Common Blue Tit, rising in frequency; this is a familiar utterance from *Cyanistes* and *Lophophanes* in Europe, *Baeolophus* in the Nearctic, and *Parus* in Europe, Africa and Asia. This churring call, too, appears to be a signal of mild alarm, and the degree to which the frequency is modulated through the call appears to signify the degree of alarm. As with the “chick-a-dee-dee” calls, it is delivered in response to a perceived threat of known location. That so many calls have been recorded in connection with situations of threat or alarm may be due to a bias in the commonly heard vocalizations, since an observer must have been present and may have been perceived as a threat. This raises the question of whether any calls exist for other situations but have not yet been documented. Perhaps in support of this is the suggestion that any unfamiliar call in a British wood, heard by a reasonably experienced birdwatcher, is likely to emanate from a Great Tit; the present author’s experience in more than 25 years of studying this species would tend to corroborate this.

The “chick-a-dee-dee” calls, and the similar counterparts given by *Parus* tits, mentioned above, recall the begging calls of the chicks of many parid species. While very young chicks either are silent or emit quiet sibilant or slightly metallic “tsee-see-see” calls, after a week to ten days the nestlings are large enough to produce loud “dee-dee-dee-dee” calls, which make the brood vulnerable to predators. Many other vocalizations are, as these, specific to the breeding season. For example, “zeedling”, which has been described as given by both Great Tits and Common Blue Tits, is a specific high-pitched call uttered during courtship feeding and, sometimes, during copulation. Females defending

Parids are essentially insectivorous birds, although in temperate environments they are more or less adapted for a seasonal switch to seeds and fruit. The **Coal Tit**, along with its congeners in *Pariparus*, tends to consume a higher proportion of insects in the diet. Like most conifer specialists in the family, this species is relatively fine-billed, an adaptation for picking prey items from amongst conifer needles and manipulating small-bodied invertebrates, in this case a spider. The proportion of different food items in the diet, particularly at the level of prey species, is determined largely by the availability and seasonal abundance of each item.

[*Pariparus ater cypristes*, Troodos Mountains, Cyprus.

the nest have been recorded as giving a snake-like hiss, this having been heard from, for example, the Sombre, Marsh and Siberian Tits, the Spot-winged and Coal Tits, the Great Tit and the Common Blue Tit; the hiss may be accompanied by a wing-flick and fanning of the tail, the combined effect of which can be quite startling. With the Coal Tit, such snake-hiss defensive calls may be given also by feathered young.

Song is, of course, the vocalization most closely associated with breeding, and that which has attracted the most research interest. As with the greater part of research on this family, however, there is a very strong bias towards the Great Tit. Experiments have demonstrated that parid song has, in addition to its mate-attracting functions, a very strong territorial function. Further, and as may be predicted from social organization (see General Habits), song seems to be most complex and strident in the flocking species, less so in the group-territorial ones, and least so in pair-territorial species, the songs of which consist of repeated, even monotonous, series of notes or simple syllables. Nevertheless, song is delivered well in advance of breeding, even by the last-mentioned species, suggesting that it has a significant advertising function. That this, like the "dee-dee-dee" calls of chicks, perhaps represents a more primitive song condition in the Paridae may be suggested by the simple songs of the Yellow-browed Tit, which sings "piu-piu-piu-piu" or "tiu-tiu-tiu", and the DNA of which places it basally to the parid phylogeny (see Systematics). Song may be delivered at any time of the day, but during the breeding season it is especially concentrated during the dawn chorus, when the sound-transmission quality of the air is best. At this time of year it is especially related also to the female's most fertile period, thus being associated with mate-guarding, as shown for the Great Tit and Willow Tit.

Simple repetitive songs of this kind occur throughout the family, but they are particularly common in the genus *Poecile*. Examples of songs given by species in the latter genus are the "tsiu-tiu-tiu-tiu" of the Marsh Tit, the "piu piu piu" of the Willow Tit, the "see-bee-see-bay" of the Carolina Chickadee, the "fee'bee-bee" of the Black-capped Chickadee, the "fee-fee-fee fee-bee-bee"

of the Mountain Chickadee, the "peeta peeta peeta" of the Mexican Chickadee and "peta-peta-peta..." of the White-browed Tit, the "tsip zee zee" of the Rusty-breasted Tit, the "psiup-psiup-psiup" of the Siberian Tit, the "chip-chip-chi-chi-chi-chi-chip" of the Chestnut-backed Chickadee, and the "tsre-tsre peee-triri-peee-triri-peee-triri" of the Varied Tit. Reminiscent of these *Poecile* songs is the one typical in Europe of a *Cyanistes* tit, the Common Blue Tit, which is a descending and slightly accelerating "tsee-tsi-brree tsee-tsi-brree".

Although parid songs are typically repetitive, their quality to the human ear nevertheless varies greatly. Whereas song elements of many tit species are described as harsh, scolding or scratchy, those of several others, among them the Siberian Tit, the Coal and Elegant Tits, the Black-crested Titmouse, and the Southern Black, Ashy, Turkestan and White-naped Tits, are considered to be "mellow". Even complex song phrases are uttered by several species, such as the White-browed Tit, Yellow-bellied Tit, Elegant Tit and Ashy Tit, and the songs of the White-shouldered Black Tit are considered to have the quality of those of *Turdus* thrushes (Turdidae).

Much research on parid song, especially with regard to the Great Tit, has been concerned with its dual advertising functions of mate attraction and territory defence. While the basic song type of the Great Tit is simple, many males have a repertoire of up to eight distinct song types. Great Tits sing at about 4–6.5 KHz, and produce songs in bursts consisting of several "tea-cher, tea-cher, tea-cher" strophes punctuated by silence. The singer may then change to a different song type. A population may have more than 40 song types in any year and, in the population as a whole, no type is produced more commonly than any other. Furthermore, the song types present in the population gradually change over years as the members change. Males differ in the numbers and types of songs that they sing, and they have more song types in common with neighbouring territory-holders than they do with more distant males. They learn some common song types before they are fully independent, but others they learn from neighbours once they have established a territory. Songs can be learned

throughout life but, although the song types produced by a male may change with time as his neighbours change, males tend to replace songs previously produced. As a consequence, a male's repertoire size may increase little with age, although populations differ in the degree to which this is so. This means that Great Tit males recognize more songs than they produce.

Song-learning and the replacement of older songs allow males to sing duets with neighbours, in a process known as "song-matching". This indicates to a neighbour that he is the intended recipient of a particular song. This may explain why males with larger repertoires tend to be better at deterring intruders. Song-matching also allows males to compare the received song with that expected, and to judge the transmitter's distance by comparing the difference, which is due to frequency-degradation with distance travelled through the wood. For this reason, and since the degradation rate varies among habitats, Great Tit songs in Europe differ more in relation to habitat than in relation to geographical separation: woodland songs recorded hundreds of kilometres apart are more similar to each other than they are to songs recorded in denser forest just a few kilometres away, the latter having lower maximum frequencies, a narrower frequency range and fewer notes per strophe.

One reason why males have large repertoires may be that they become habituated to a song and, in time, come to ignore it. Although there is good evidence for this, there is also good evidence that males with larger repertoires are fitter individuals. Males which sing more songs tend to be socially dominant, to have a greater chance of breeding, and to produce more and heavier chicks, and more recruits, than do males with smaller repertoires. Great Tit males with large vocal repertoires also sing longer strophes and display less "drift", for example in frequency.

Females are able to tell much from song, which gives an honest signal of male quality. Female Great Tits treated with a female hormone to heighten their interest in male stimuli seem, however, to prefer the songs of local males over those recorded elsewhere. This complements observations that females are more likely to pair with males having songs similar to, but not the same as, their own father's songs. Since females are known to prefer to pair with local males, this suggests that they take an interest in

a male's songs not just in order to assess fitness, but also to assess how closely related they are; this would be important, as chicks produced by parents that are related to each other are, as a result of genetic difficulties, less likely to survive. Female Great Tits, too, may sing, but specifically to attract the attention of the male, for example to help her in defending the nest.

## Food and Feeding

Parids are generalist, opportunistic, invertebrate-eating birds that, outside the breeding season, incorporate, to a greater or lesser degree, seeds in the diet. Indeed, even the most aberrant member of the family, the Yellow-browed Tit, takes small seeds. The chicks are raised largely on tree-defoliating caterpillars (Lepidoptera). Naturally, the precise list of food species taken, either when breeding or at other times of the year, varies from one parid species to another, but even the most cursory inspection of the data indicates the generally catholic tastes of the tits and chickadees. This may suggest that the average parid will eat practically anything with more than four legs if small enough to handle, but this perception is profoundly flawed.

Detailed investigations of the foraging behaviour of the Great Tit, probably the species with the greatest dietary breadth, indicate that complex decision-making processes are involved in its foraging, and that generally this species follows "rules of thumb" that result in its foraging optimally in terms of energy management. For example, when foraging for prey for nestlings, Great Tits do not simply search for caterpillars, but select those caterpillars that are small enough for chicks of the particular age at that time, so that prey size increases over the brood's first six days from hatching; this is integrated with an assessment of the distance travelled from, and the time spent away from, the nest, the adults returning with larger prey as the time away from the nest increases (following the rules of the "Marginal Value Theorem" of central-place foraging).

So, apart from variation in food availability, the main constraints on parid trophic ecology stem from five factors. These are: (i) optimal-foraging rules; (ii) specific dietary requirements

In northern latitudes, parids are rarely seen drinking directly from water sources, tending to meet their needs through the water content of insects and seeds.

In more southerly climes, and drier habitats, however, they are perhaps more regular visitors to ponds and streamsides. This **Carolina Chickadee** is crouching at the edge of a shallow pool, almost certainly drinking, but also possibly collecting small pieces of calcareous grit. Both sexes eat grit to aid digestion, and breeding females seek grit and other calcareous material, such as fragments of snail shell. This helps them to form eggshells, and aids in the development of nestlings.

Maslowski Productions]

Parids hang upside-down to inspect awkward locations when foraging, but when no foothold is available a further technique is used, sometimes termed "reguline" foraging, but better known as hovering. This technique is frequently used by the smaller parids, allowing them to find hidden insects on the underside of foliage on outer branches, for example, or to steal prey items from spiders' webs. The benefits of this behaviour extend beyond food. With water almost impossible to find in freezing conditions, this **Black-capped Chickadee** is hovering to quench its thirst at the tip of an icicle.

[*Poecile atricapillus*  
*practicus*,  
Freeville, New York, USA.  
Photo: Marie Read]

Most parids are socially monogamous with lifelong pair-bonds. Breeding territories are established at the beginning of each reproductive season, but the first signs of courtship are often seen earlier. A male **Chestnut-backed Chickadee** has delivered a small insect to its mate in a pre-breeding ritual known as "courtship feeding". This probably serves a dual purpose, being on one hand an honest signal of male quality, and on the other a nutritional supplement for the female while the eggs are developing. Females of all parids beg for food using the same high-pitched "zeedling" call and wing-shivering display as used by fledglings.

[*Poecile rufescens barlowi*,

at certain times of the year, such as small snails taken for the calcium by females during egg formation; (iii) the species' morphology, such as bill shape and size, legs, and so on (see Morphological Aspects); (iv) direct and diffuse competition with other species, including other parids, which may determine the specific foraging location or niche; and (v) the range of prey-handling techniques in the parid behavioural repertoire, which is remarkably uniform through the family.

The large numbers of caterpillars delivered by parids to their chicks can make a significant impression on the populations of their prey. This is indicated, for example, by the fact that Great Tit nestlings were heavier at fledging in an area where Common Blue Tits, which take the same prey but tend to nest slightly earlier, were removed, but lighter in an area where the Common Blue Tit nestlings were added into the resident Common Blue Tits' nests.

A major limitation on the ability of parids to reach invertebrate prey is imposed by the conformation of the bird's body mass, legs, wings and bill. Larger species, such as the Great Tit and the Tufted Titmouse, tend to hop-forage more on or near the ground, searching for seeds such as beech mast hidden in the autumn leaf litter, and to use hover and hanging postures far less frequently than the smaller, more agile species within the same foraging flock. A useful distinction has been applied here, especially in connection with the Nearctic parids, between, on the one hand, the foliage-gleaning guild, which generally includes the chickadees together with kinglets, *Dendroica* warblers (Parulidae) and the smaller titmice such as the Bridled Titmouse, and, on the other hand, the bark-foraging guild, consisting of the larger titmice together with, among others, nuthatches and American Treecreepers (*Certhia americana*).

An important type of behaviour associated especially with the smaller parids is that of hanging, in which the bird hangs by one or both legs, upside-down, in order to inspect a twig, leaf, bud or the like from every angle for small invertebrates. The frequency of this behaviour is so closely tied to the bird's weight that even within species, as noted in *Periparus* and *Lophophanes* tits, heavier individuals tend to use it less frequently than do lighter ones; moreover, an individual tit employs this behaviour less often later in the day, when its fat reserves have built up,

than it does earlier in the day. The frequency of hanging is related also to specific leg morphology (see Morphological Aspects). In various studies, hanging has been noted as utilized for less than 10% of the foraging time by such species as the Great Tit and the Tufted Titmouse, but more than 20% of the time by the Common Blue Tit and the Bridled Titmouse. Hanging is specifically mentioned as a foraging method for all *Cyanistes* species, for six of the 13 *Poecile* tits, but for only two of the 23 *Parus* species. As a means of inspecting awkward locations, an extension of hanging is the technique of hovering, or "reguline" foraging, which is similarly much more frequently practised by the smaller parids; furthermore, the larger parids, when they do hover, tend to do so for shorter periods. Many of the smaller parids, especially those in the genera *Poecile*, *Periparus*, *Cyanistes* and *Sylviparus*, but also a *Parus* species, the Black-lored Tit, also pursue insects in flight in the manner of an Old World flycatcher (Muscicapidae).

These types of behaviour are typically associated with glean-ing, in which the bird simply pecks the prey item from the substrate, whether leaf, twig or bud. Although this is the most common acquisition technique, that of probing, in which the bill is inserted in bark, in conifer needles, or between scales of a bud in order to remove prey, may also be important. Interestingly, Great Tits have been recorded as using a pine needle held in the bill to probe for larvae in a hole, although this is extremely uncommon. The ability to probe is closely related to the depth-to-length ratio of the bill, known as the bill index or the bill aspect ratio, and this behaviour is therefore used much more frequently by *Periparus* and *Lophophanes* than by *Poecile* and *Parus*. Moreover, its use varies within species, in that female Great Tits, which in some populations have a finer bill than males, tend to probe more frequently. Similarly, these fine-billed species, and fine-billed individuals, take smaller prey on average than do the heavier-billed species or individuals; and longer-billed, and thus finer-billed, female Great Tits tend to deliver more small caterpillars to their broods than do females with a shorter, stouter bill. Related to the subject of food-item size is the matter of food-handling, since larger prey and hard-coated seeds require significant preliminary processing, whereas small prey or seeds can be ingested with little or no such treatment.

An aspect of behaviour common to most parids, but observed especially for the heavier-billed *Parus*, *Baeolophus*, *Poecile* and *Cyanistes* species, and also for the Black-breasted Tit, notably the largest, heaviest-billed *Periparus*, is that of hammering or "hold-hammering". In this, the tit holds the item fast under one foot, when dealing with a caterpillar or similar prey, or between both feet, when handling beech seed, for instance, and repeatedly strikes the food vertically from above with the bill. The power of this hammering should not be underestimated. Although it may take him 20 minutes, a male Great Tit can open a hazelnut (*Corylus avellana*) in this way. The Black-breasted Tit may even use an "anvil", placing nuts in a crack in a branch in order to hammer them open.

Hold-hammering is utilized also to deal with larger caterpillars, in order to kill them before removing the head, thereby making the prey safe for a chick to eat. Great Tits, when processing caterpillars in oak woods, have been recorded also as drawing out the gut after removing the caterpillar's head, and discarding this before feeding chicks, although they do not do this if swallowing the prey themselves. The purpose of this procedure is to remove the tannins that may have accumulated in the caterpillar's gut, and which are known to reduce the growth rate of chicks ingesting them. Associated with these aspects of behaviour is an undoubted intelligence. For example, Great Tits have been shown to have a well-developed ability to solve problems by "insight" learning, in other words, to make decisions through insight into a problem, rather than through mere trial and error. This gives the parids enormous behavioural flexibility, which has contributed to their ability to exploit new resources. Common Blue Tits, for instance, have been observed to tap dead, hollow hogweed (*Heracleum sphondylium*) stems in winter to find overwintering grubs, and then to open them by hammering where the stem is not hollow. Similarly, Azure Tits have been observed to open plant stems in search of larvae, and in Africa the Southern Black Tit taps dry seedpods to enable it to identify those that contain chalcid wasp larvae. In America, Mexican Chickadees hammer open oak galls in order to remove

parasitic insect larvae, as do Great Tits in Europe, and experiments have shown that Great Tits can distinguish visually between viable and inviable beech seeds, that is full or empty ones, a skill which must save much time when they are searching for food. All these are examples of the tits' ability to read signs indicating the presence of hidden food, behaviour that has undoubtedly contributed to the family's success.

This adaptability is reflected in the worldwide use made by parids of birdtables and feeders provided by humans (see General Habits). Particularly favoured foods are peanuts, especially for *Parus*, *Periparus* and *Cyanistes* tits, sunflower seeds, for *Poecile* and *Baeolophus* species, and sources of fat such as suet or cheese, which are popular with many species in this family. Such provisioning is known to make a significant difference to the overwinter survival prospects of many parid species, and especially to the subordinate members of groups, which are frequently outcompeted in flock situations. For example, food provided by humans can increase the survival probability of juvenile chickadees by more than 10% over that recorded in unprovisioned groups. In Europe, the overwinter survival rate of Great Tits, especially of juveniles, is substantially higher when there is a good beech-mast crop, which often results in an increase in the breeding population in the following year. Failure of this and other crops, such as pine cones, can lead to irruptive movement of tits in Europe and Asia, as typified by the Siberian, Coal, Common Blue, Azure, Great and Yellow-bellied Tits, and by Boreal and Chestnut-backed Chickadees and titmice, especially the Tufted Titmouse, in North America (see Movements).

That the artificial provisioning of food has a significant effect on flocking species also is indicated by the way in which it influences the birds' daily management of their winter fat reserves. In the winter months, parids at northern temperate latitudes accumulate fat reserves as a means of helping them to survive the long, cold nights. Small species, such as parids, experience a rapid turnover of energy reserves and cannot store enough for more than a day or so. Consequently, fat reserves must be built up daily for use overnight. The additional weight of fat, however, brings a

Like other tits in the Nearctic, Palearctic and Oriental Regions, the **Common Blue Tit** builds its nest on a pad of moss. The depth of this pad is variable, depending on habitat, temperature and the time available for construction, with the pads in earlier nests being especially copious. For much of the nest-building phase, the female busily gathers moss and dumps it into the nest cavity. She enters occasionally to shape the pad with her breast, and when the moss lies deep enough she fashions a rough nest-cup lined with hair. Feathers are also collected, but they are usually laid over the eggs rather than woven into the base structure.

[*Cyanistes caeruleus caeruleus*, Bavaria, Germany. Photo: Konrad Wothe]

cost when the bird is in the presence of avian predators, such as the smaller *Accipiter* hawks, and tits attempt therefore to carry an optimum fat load that takes account of the probabilities of starvation and predation, rather than simply carrying the maximum possible. For this reason, dominant Great Tits, such as males, carry less fat than do subordinate individuals, such as females, because their status gives them greater access to food. Great Tits also carry more fat on colder days, when the starvation risk is likely to be increased, and they reduce their fat load when food is provided predictably, for example at a birdtable. In relation to this, residents carry less fat than do transients or "floaters". Similar observations have been made for group-territorial species such as Willow Tits and Black-capped Chickadees, for Tufted Titmice and for Coal Tits.

An alternative strategy to the storing of fat reserves is that of food-hoarding, or caching, especially of seeds in winter, although these caches are not necessarily treated as alternative stores by the birds. For example, Tufted Titmice, when their food supply becomes less predictable, increase both their caching rates and the size of their daily fat reserves. The distribution of the food-caching habit across genera, being especially prevalent in *Poecile*, *Periparus*, *Lophophanes* and *Baeolophus* species, is consistent with the pattern of two broad modes of caching behaviour: short-term caching by subordinate species, such as the Marsh Tit and Coal Tit, which in mixed-species flocks may benefit from having a cache that they can exploit after their competitors have left; and long-term caching by species for use during the harder months of winter, as by the Willow Tit, and perhaps also by the Tufted Titmouse, which is generally socially dominant. In general, as illustrated by the Willow Tit, caching behaviour increases as conditions worsen, subordinates store at greater intensity than dominants, but dominants increase their hoarding effort relatively more than subordinates as conditions worsen. Food-caching therefore reflects the birds' social and trophic environment, as does fat deposition.

While long-term caches consist typically of seeds, short-term caches can include invertebrates. For example, European Crested

Tits frequently store invertebrates that are still alive, but have been incapacitated by the bird. The association between food-caching and a pair-territorial or group-territorial social organization (see General Habits) is important for species which use the memory in order to refind caches. This is no trivial matter for birds that cache more than 40 seeds per hour, as the Marsh Tit does, or 200 per day, as the Willow Tit does; indeed, the estimated total numbers of items stored during the course of a year may reach half a million in the cases of the Willow and Siberian Tits. The proportion of seeds retrieved varies hugely, from just 15% by Siberian Tits to as much as 95% by Willow Tits, the latter representing a truly staggering mental performance. In order to achieve this, the tits must have a home range that is very stable over a long period, thereby enabling them both to build up an intimate knowledge of the area and to be in the same space to retrieve the food in the future. They must also have some reasonable expectation that their caches will not be stolen by other birds, rodents and the like. Some individual parids, notably some Great Tits, specialize in watching hoarding Marsh and Coal Tits and then stealing their caches. The Coal Tit, which stores food and is a flocking species, provides an exception to the general association between winter territoriality and food storage. The frequency of caching, however, varies markedly among Coal Tit populations, and it appears that, where they do hoard, the tits' rate of recovery of these items is rather poor, suggesting that, for this species, memory may not play so great a part in the relocating of items as it does for *Poecile* species. The extent of food-storing among *Periparus* tits is unclear: apart from the Coal Tit, the Yellow-bellied Tit is the only other member of this genus known to store. For *Periparus*, storing is probably a response to the birds' low social rank within mixed-species flocks, rather than being indicative of any long-term storage requirement.

Competition for food, including caches, among parids can result in individuals making shifts in foraging niche when in the presence of dominant individuals or species. For example, Coal Tits and Willow Tits tend to feed in more exposed parts of the tree canopy, where the predation risk is greater, when they are in

All parids are cavity-nesters and most of them use natural holes in trees, usually 2-5 m above ground. The Afrotropical species, such as the **Southern Black Tit**, tend not to build a pad of moss to support the nest, presumably because moss is scarce in the arid and semi-arid regions of Africa. Instead, the pad is built from fine plant fibres, lichens and animal hair.

As with other tits, the female builds the nest alone. The Southern Black Tit often breeds co-operatively: more than 50% of pairs are assisted in territory defence and brood rearing by up to three male helpers, probably offspring from previous broods.

## Breeding

Much of the immense research effort carried out on parids has focused on the ecology and evolutionary aspects of breeding. Almost every aspect of the reproduction of the Paridae has been scrutinized, from the timing and size of the clutch, and the effects of population density and nest parasites on breeding success, to the function of pigments on their eggs, and the female's sex allocation of eggs/chicks on the basis of her mate's attractiveness.

Breeding places great demands on birds for energy and protein. In general, therefore, parids have a distinct breeding season, which is timed to coincide with the maximum availability of food in the territory. Although many parids take a large range of plant food outside the breeding season, the chicks are raised on a diet of arthropods, and most species show a preference for caterpillars with which to feed the brood. As parids rarely drink water directly, and do not bring water to the brood, a strong attraction of caterpillars may be their relatively high water content, in addition to their soft and relatively digestible body. For many parid species, the timing and abundance of this food, such as the intense flush of caterpillars in broadleaf woodland in the northern spring, is a determinant of many key aspects of reproduction, including the timing of breeding, the size and number of eggs laid, growth performance and fledging success of the brood, and the decision to lay a second clutch. The precise timing of breeding varies among species in relation to the differences in local food availability. In addition, smaller species tend to start laying a few days before larger species at the same site, because the smaller female's absolute threshold of food required to form eggs is passed sooner than is that of the larger female; for example, Coal Tits lay before Common Blue Tits, which lay before Great Tits do. Nevertheless, while the precise timing is strongly determined by local spring temperature, which determines the timing of insect emergence, parid breeding throughout most of the

*While most tits use natural cavities, many species in the genera Poecile, Baeolophus and Lophophanes excavate their own nest-hole. In the Willow Tit, for example, both sexes dig out a cavity in rotting wood, although they may adapt an existing cavity made by a woodpecker (Picidae); this individual is using a typical woodpecker hole in a Scandinavian birch (Betula). Excavator species tend to be monogamous, with lifelong pair-bonds. It is possible that they are also locally subordinate species, with the best natural nest-sites being occupied by their dominant relatives.*

[*Poecile montanus borealis*, Liminka, Finland.

the presence of dominant European Crested Tits than when foraging in single-species groups, and Great Tits reduce the use of middle-height canopy when accompanied by Varied Tits. Similarly, immature Willow Tits and European Crested Tits forage in more risky sites in the presence of dominant conspecifics than when alone, and adult European Crested Tits generally cache items in those parts of the tree in which they also forage, whereas immatures were found to cache seeds in sites other than those where they were foraging. Coal Tits likewise tend to cache items in places away from where they are foraging in the flock. Studies of parids have established that birds are prepared to accept a greater risk of predation as the starvation risk increases. This was demonstrated in a study of Great Tits feeding on beech mast, where the tits searched in increasingly exposed locations as the winter progressed and the seed crop diminished. Many parid species with access to a predictable food source, as at a birdtable, increase their fat reserves, and hence also their mass and mass-dependent predation risk, at the end of the day, when the looming overnight starvation risk becomes a near-certainty, compared with an uncertain risk of predation, although hawks may also learn that this is a good time to visit the birdtable.

Long-term seed-storers at higher latitudes and for which the cache is critically important for their survival, such as Willow and Siberian Tits and Boreal, Mountain and more northerly Black-capped Chickadees, take care to select caching sites that are above the likely level of snow. Cache sites include hollows behind loose bark, crevices in tree trunks, bundles of dead leaves and pine needles under branches, inside bud capsules or in lichen, but more rarely in the ground. In contrast, Marsh Tits, which generally retrieve their cache within 48 hours, frequently store items close to the ground in wood piles, under moss clumps, and in leaf litter, as well as in holes in the ground and behind loose bark and similar places. Although the purpose of seed stores is generally that of aiding overwinter survival, a few species store food also during the summer, or, as in the case of the Varied Tit, may use stored food to sustain them while they forage for food for the chicks during the following breeding season.

*Many parids have been recorded nesting in man-made structures, including buildings, drainpipes, vehicles and streetlamps. The Great Tit, with its bold and inquisitive nature, is especially predisposed to a life alongside mankind, and mankind's paraphernalia. It has adapted so well to village life and suburbia that almost any suitable aperture can double up as a handy nest-site, sometimes with amusing consequences: in this case a pair has chosen to nest in a British letterbox, causing a slight disruption of the local postal service.*

In most tits, including the Marsh Tit, incubation is undertaken solely by the female. A typical incubation schedule is 50 minutes on the nest, followed by 10 minutes off the nest for feeding and sanitation, and so on. Periods of continuous incubation are increased when the male feeds the female on the nest, as happens in many parids. The clutch temperature is typically maintained above 30°C with body heat delivered through bare skin on the belly, the "brood patch". The first eggs are warmed at night by the roosting female, but the incubation period does not begin in earnest until the last egg has been laid.

Nearctic, Palearctic and Oriental Regions occurs between March and July, with the most intense activity between April and June. The few exceptions to this general rule, such as the Black-crested Titmouse in the USA, the Canary Blue Tit on the eastern Canary Islands, and the Yellow-cheeked Tit in Thailand, have more southerly distributions, experiencing hot, dry summers, and may start breeding in February. Because the timing of breeding is driven by spring temperature, which has risen over the past 30 years, many parid species at temperate latitudes now start egg-laying some 2–3 weeks earlier than they did before 1980.

The breeding biology of most tit species in Africa is poorly known, but the breeding season appears to vary with latitude, generally falling in spring farther from the equator, and being distinctly less seasonal nearer the equator. Hence, north of the equator, White-shouldered Black Tits and Somali Tits breed during January–June and February–June, respectively. The southern species tend to have a more protracted season, influenced by the coming of rains, the Grey Tit breeding in August–March, the Ashy Tit in September–April, Carp's Black Tit in October–May, the Miombo Tit in August–December, Rufous-bellied and Cinnamon-breasted Tits in September–December, and the Southern Black Tit in August–January. Such evidence as birds in breeding condition suggests that, closer to the equator, the White-winged Black, White-bellied, Dusky, Red-throated and Stripe-breasted Tits may breed throughout the year.

Most parids are socially monogamous, and pair for life. The only species for which polygamy is known to be significant is the Common Blue Tit, nesting at high densities of, for example, more than one pair per hectare. Nevertheless, extra-pair paternity has been detected in other species. In studies of the Great Tit, genetic screening has revealed that young fathered by a male other than the territory-holder, or putative father, occurred in 8.5% of nests and accounted for 3.5% of offspring in the Netherlands, in 17% of nests (14% of offspring) in the UK, and in up to 44% of nests (8.6% of offspring) in Germany. Similar studies of the Coal Tit in Germany have revealed much higher rates of extra-pair paternity, with 75% of nests affected and some 25% of young

resulting from extra-pair fertilizations. No evidence was found that breeding density influences the rate of extra-pair paternity. Rather, it appears to have been some aspect of the putative father's fitness or "attractiveness", such as body size, that determined the likelihood of his being cuckolded. Although much rarer among pair-territorial and group-territorial species, extra-pair copulation has been recorded also for the Willow Tit.

The onset of breeding is typically marked by the break-up of the winter flocks, which is driven by the increasing frequency of aggressive interaction as males attempt to establish territories, and pairs form or re-form. With flocking species, many territories will be established beyond the normal home range of the flocks, because the food requirements for the winter flock differ starkly from those of the nestlings; for example, beech mast is fine for adults in the non-breeding season, but beech is a poorer tree than oak for the caterpillar prey required to feed the chicks. In pair-territorial and group-territorial species, the territories more often fall within the home range of the flock. Under both main systems of social organization, a number of first-year individuals will fail to establish a territory and to breed, because of a lack of suitable habitat. With flocking species, these generally become floaters, dispersing more widely in search of a territory; with group-territorial species, on the other hand, they may even co-operate in the raising of the brood of the alpha pair, as occurs among, for example, Bridled Titmice and several African *Parus* species. For most pair-territorial and group-territorial species, pair formation probably occurs before the winter, or the birds retain partners from the previous year. With flocking species, the timing of pairing seems more variable, and, while pairs from the previous year usually re-form, it is not clear whether loyalty is to a partner, rather than to a territory; divorce occurs frequently if breeding failed in the previous year. In these species, males are typically more loyal to a territory than are females, and from the available evidence brood desertion is generally believed to have been initiated by the female. Hence, females divorce males and their territories, and in mate selection it appears generally to be the case that the females select the males.

Mate-preference involves a number of facets, including song quality, body size and plumage badges, any of which may indicate a bird's health and fitness. The last two are displayed through specific exaggerated postures, especially head-up displays by *Parus*, *Periparus* and *Poecile* species, which present fitness-indicating badges. Females may themselves, however, occupy a position in a social hierarchy, and so may not obtain their preferred partner. Two post-mating indicators of the female's preference, revealing whether or not she paired with her preferred male, have been discovered through genetic screening of populations. First, poorer-quality males, such as smaller male Great Tits, and male Common Blue Tits with a duller blue crown, are more likely to have in their nests chicks that they have not sired, indicating that the female has accepted an extra-pair copulation. It should be noted that, in order to avoid this, males of these species guard their mates at the receptive egg-forming stage, so that extra-pair young indicate a failure by the male to guard his mate. Secondly, it has become clear recently that female Great and Common Blue Tits can adjust the sex ratios of their broods, and in so doing skew the ratio in favour of sons when they have an attractive partner.

Courtship behaviour generally involves courtship feeding. With the Black-capped Chickadee, this can start long before breeding territories are established, and this probably helps to inform the female of the male's ability to provide for her and the subsequent brood. For this and other species, however, courtship feeding may provide the female with essential additional food for the process of egg formation. Female Common Blue Tits may receive a third of their food from the male, which typically gives her the larger prey that he catches, during this period. To solicit this from the male, females of all parid species studied use the same high-pitched "zeedling" call and wing-shivering display as are used by fledglings when soliciting food from the parents. The contribution that males make to the female's nutrition during egg formation is likely to be considerable in the case of flocking species, females of which typically lay the equivalent or more of their own body weight in eggs within fewer than ten days.

All parids nest in holes, but the locations of these vary. Although the majority of the species favour a tree hole if such is available, many *Poecile* and *Baeolophus* species and the two *Lophophanes* tits excavate their own nest-hole in dead wood, and the nests of several *Periparus* species, and of the Ground Tit, occupy holes in the ground, such as those made by mice (Muridae), or on a sloping bank to prevent water entry. Excavated nest-holes are usually prepared by both members of the pair, but the nests are typically built by the female alone, as is the case with most other parids. Two *Parus* species are notable exceptions to this, these being the Grey Tit of southern Africa and the Black-lored Tit of India; with these two, nest-building is undertaken by both members of the pair, although it is not clear why they should differ in this respect from all other parids.

Many members of the family have been recorded as nesting in holes in man-made structures, including buildings, vehicles, letterboxes, and streetlamps and street signs. It is no surprise, therefore, that no fewer than 26 species, comprising ten *Poecile* species, one *Periparus*, one *Lophophanes*, five *Baeolophus*, seven *Parus* and two *Cyanistes*, have been recorded as using nestboxes. Further, the species missing from this list, such as most *Periparus* tits, inhabit primarily regions where boxes have never been provided. Since several of these species also use artificial nest-sites, the full list of parids that may use them is undoubtedly larger. It is notable that so many of the "excavator" species will use nestboxes if these are available, although, to encourage the birds to use them, it may be necessary to fill the boxes with sawdust to be excavated. There is some evidence that excavators tend to be locally subordinate species, the dominant species taking the best natural nest-sites.

The reuse of nest-holes in subsequent years is a common practice of many species, even when, to the human observer, alternative sites may appear to be available. Studies based on populations nesting in nestboxes have suggested that, because boxes used in previous years may have large parasite infestations, especially of fleas (Siphonaptera), which can reduce the growth and viability of nestlings, the adults should avoid the reusing of sites in con-

The breeding biology of the **Siberian Tit** has been studied at two sites in Finland. It was found to lay clutches of up to 11 eggs, which is typical for temperate parids. The chicks are fed by both parents for 19–20 days with breeding success of 4–6 fledged young per nest. This species lives in high-latitude conifer forests, and likely represents a return invasion of the Old World by a New World *Poecile*. This can be inferred from the fact that it is much closer, both genetically and in plumage characteristics, to the Nearctic Chestnut-backed (*Poecile rufescens*) and Boreal Chickadees (*Poecile hudsonicus*) than it is to any Palearctic or Oriental species.

[*Poecile cinctus lapponicus*, Kuusamo, Finland.  
Photo: Dick Forsman]

The female **Coal Tit** builds the nest alone, almost entirely from moss, usually in a hole in a tree trunk or an old stump. A variety of other crevices are sometimes used, including holes in walls or man-made nestboxes, as seen here. Some pairs even nest on the ground amongst stones or tree roots, or in mouse-holes. The brood is fed by both parents for 18–22 days, with breeding success being 50–90% in terms of eggs laid, but approaching 100% in terms of eggs hatched, at least in some habitats. In optimum situations the breeding territory seems to be very small, perhaps 100 m in diameter.

[*Periparus ater vieirae*, Almarza, La Rioja, Spain.  
Photo: José Luis Gómez de Francisco]

secutive years; and, certainly, experiments have shown that, if given a choice, Great Tits prefer neither to roost nor to nest in a hole containing an old tit nest. Studies of parids in natural nest-sites, however, suggest that parasite effects are often less marked in such sites, perhaps because of differences in micro-climate between natural nest-sites and artificial ones, and nest-site security from predators is probably a more important concern. Excavation of a nest-hole may both reduce parasite infestation and prevent predators from learning the locations of nest-sites, although the intense activity of excavation itself may attract the interest of predators.

The nests of seven parids still await full description, but those of the other 49 are remarkably uniform across the family and throughout its range. In species of the Nearctic, Palearctic and Oriental Regions, the base of the nest consists of a pad of moss, which may vary in depth from 1 cm to 8 cm, depending on species, temperature and the time available for its construction, the pad being deeper in earlier nests. Hence, this moss base is common to all *Poecile*, *Lophophanes* and *Baeolophus* species, to Palearctic and Oriental *Parus* except for the White-naped Tit in India, and to the Yellow-browed and Sultan Tits in the respective monotypic genera *Sylviparus* and *Melanochloa*. In *Cyanistes*, an exception is the Canary Blue Tit, which, instead of using moss, which is scarce within its range, generally employs grass or other dry plant material, together with hair and feathers. Although hair is used as a lining by all parids for which the nest is known, the pattern of usage of feathers in nests is unclear. Feathers are found regularly in the nests of six *Poecile* species, one *Periparus*, one *Lophophanes*, two *Parus* and two *Cyanistes* species, and occasionally in nests of a further one *Periparus*, three *Parus* and two *Baeolophus* species. The pattern of feather usage among species suggests that feathers do not serve an insulation function, and a possible alternative explanation is that they act as a distraction for predators attempting to find eggs. Certainly, human observers find it difficult accurately to count Common Blue Tit eggs in a pile of white Common Woodpigeon (*Columba palumbus*) feathers.

Perhaps the most complex nests are those of *Baeolophus*, which can contain moss, leaves, grass, hair and feathers, bark strips, and also, in the case of the Tufted and Black-crested Titmice, snakeskin. Grass, moss and hair are used also by the

Ground Tit, reinforcing its affiliation with the Paridae, rather than the Corvidae (see Systematics). The nests of four African *Parus* species have yet to be or on described in full detail, but those of the eleven others reflect the dry conditions of the nest-site in their composition, as they generally contain grass and/or vegetable down and hair, occasionally with wood chips as a base; in addition, feathers have sometimes been found in the nests of Grey and Ashy Tits. The grassy nests of southern parids tend to be shallower than the mossy constructions of the more northerly species.

Nest-building for all members of the family appears to involve the female in piling in the base layer, for example of moss, and then using her breast to push this into the corners of the nesting cavity. When the layer is deep enough, a rough nest cup is shaped, again by using the breast, and this is then lined with hair. Feathers, if used, tend to be piled in on top of the eggs, rather than forming a lining or being incorporated in the base structure. Females usually roost in the nest-cavity from before egg-laying through almost to the time when the brood fledges. Males may roost in another, often smaller, tree hole elsewhere in the territory or, later in the breeding season, simply on a branch close to the trunk of a tree.

While the eggs of a few parids have drawn much attention from biologists, in contrast those of two *Poecile*, two *Periparus* and five *Parus* species have not yet been described. Although small in absolute terms, parid eggs are large in relation to the size of the bird. Across the whole family, egg mass increases strongly and linearly with the body mass of the bird. For example, the Coal Tit has a body mass of about 9.8 g and an egg weight of about 1.15 g, corresponding approximate figures for some other tits being 11.6 g and 1.25 g for the Black-capped Chickadee, 16.6 g and 1.7 g for the Great Tit, 21.8 g and 1.84 g for the Tufted Titmouse, and 41.5 g and 2.51 g for the Sultan Tit. The relative mass, however, declines linearly with increasing bird mass, from 11.7% in the Coal Tit to 6% in the Sultan Tit. The eggs represent an enormous investment. Parids obtain most of their water from that contained in food, rather than by direct drinking, yet their eggs have a high water content of some 81.5%, which itself may be a heavy cost in drier environments. The remaining dry matter is about 43% protein and about 33% lipid by mass, which, summed over a clutch of 5–10 eggs, represents about 0.7–1.3 g

A Mountain Chickadee arrives at its nest, ■ disused woodpecker hole in an old dead pine, up in the Rocky Mountains. It is difficult to say whether this is a male or a female, as the species is sexually monomorphic. Both adults feed the brood, although most items are collected by the male, and the nestlings fledge after a period of 20–21 days. The young remain dependent on the adults for ■ further 21 days, after which they disperse. Like many other parids, this species first breeds when it is only one year old. The maximum recorded longevity is 10 years.

[*Poecile gambeli gambeli*, Colorado, USA.  
Photo: S., D. & K. Maslowski/  
FLPA]

of protein and 0.5–1 g of fat, in addition to the calcium required for the eggshell. The possibility that food availability may limit the female's ability to produce eggs is indicated by the fact that, as found with the Great Tit, for example, eggs laid earlier in the season tend to be smaller than those laid later. On the other hand, eggs are larger if the air temperature over the four days prior to laying, the time required for an egg to develop, is higher, which would encourage insect emergence. Calcium availability is perhaps the most significant nutritional constraint on egg formation, and female tits, during the laying period, search specifically for high-calcium prey such as snails, which they do not eat at other times of the year. Pieces of snail shell can often be found in the nest, taken in by the female during egg-laying, or to feed to the chicks, which also have a high demand for calcium. Severe calcium deficiency, as, for instance, in acid areas, results in shell-thinning or even, in extreme cases, in shell-less eggs being laid.

Parid eggs are generally white, with red-brown spots or speckles of protoporphyrin pigment. There is, however, some variation on this general theme. A given species may sometimes lay pure white eggs, and this is, indeed, the normal condition for the Ground Tit, the Bridled Titmouse and the Yellow-browed Tit. Although two of these species are close to the base of the parid family tree, pure white eggs do not represent a primitive condition, because, although they are typical of the Remizidae, the sister-taxon to the Paridae (see Systematics), parid-like speckled eggs are typical also of other closely related families, including Sittidae, Aegithalidae and Sylviidae. The white of the eggshell often has a slightly pinkish cast prior to incubation, possibly because of light transmission through the egg, which ceases when development starts. Variation in the colour of the spots has been noted especially on eggs of the White-winged Black and Southern Black Tits, the Miombo, Ashy, Grey and Yellow-cheeked Tits and the Sultan Tit, on which the spots are often greyish. This may be because of incorporation of protoporphyrin within the shell, so that it is partially obscured by shell calcite, but this requires investigation.

When present, the pigment spots vary greatly in intensity, both between clutches, the pattern of which tends to be more or less specific to the female laying them, and within clutches, since the eggs tend to be less intensely spotted early in the laying se-

quence of the clutch. Speckling is usually most marked at the blunt end of the egg, and often forms a ring around the air-cell, close to the broadest part of the egg. Recent studies of the eggshell speckling of Great Tit eggs suggest that its function is that of strengthening the shell, and of compensating especially for calcium deficiency. The pigment, which may act as a shock-absorber within the shell, specifically marks patches of thinner eggshell, and Great Tits laying in areas with lower soil-calcium availability, and hence lower snail densities, laid thinner, more intensely speckled eggs. There is a suggestion also, from work on the Common Blue Tit, that the female's condition, in terms of her immune-system function, may be reflected in eggshell speckling, but this could also indicate her nutritional status, perhaps affected by the availability of calcium. A further function of the eggshell speckling may be that of indicating the egg sequence to the female, since her incubation behaviour appears also to take account of the speckling patterns, which, in indicating eggshell thickness, must also indicate the propensity of the individual eggs to lose water through incubation. What does seem clear, however, is that eggshell patterning in the Paridae does not serve to camouflage the eggs from predators, as the eggs are clearly visible in the nest unless, as recorded for several species, the female, during the laying period, covers them with nest material before leaving the nest, in which case they are not exposed to predators.

Once laying begins, the eggs are typically laid at daily intervals until the clutch is complete, whereupon incubation commences. Gaps in laying may sometimes occur in response to short-term food shortage. Parids lay large clutches, but clutch size varies greatly both within species, in response to immediate environmental circumstances, and among species. Two broad patterns, which are not mutually exclusive, can be discerned. First, species at higher, temperate latitudes tend to lay larger clutches than those at lower, tropical latitudes. Within the genus *Parus*, for example, clutches of twelve eggs are common for the Great Tit in Europe, whereas eight eggs would be a maximum for Oriental *Parus* species, most clutches of which are of 3–7 eggs, and African species lay fewer than six eggs, most clutches containing 2–4 eggs. Similarly, the European Crested Tit's maximum clutch size of eleven contrasts with that of five for its Himalayan

The Great Tit has been described as the best-known avian species in the world. Its high population density and ready use of nestboxes make it a convenient subject for scientific research, and some populations have been producing data for decades. These data sets provide a unique insight into subtle ecological mechanisms, such as the processes underlying dispersal in young birds, and the timing of egg-laying. They show, for example, that the Great Tit precisely synchronizes the hatching of its eggs with the brief surge of invertebrate prey in the Palearctic summer.

Fernández Díaz-Formentil]

congener the Grey-crested Tit, and the 13-egg clutch of the Coal Tit is much larger than the generally more modest clutch sizes of the Himalayan *Periparus* species, which consist mostly of fewer than seven eggs. Secondly, pair-territorial and group-territorial species tend to lay smaller clutches than do flocking species. Hence, while clutches of more than nine eggs are typical of Great, Common Blue and Coal Tits in Europe, they are always smaller than this in Nearctic *Baeolophus* species. At a given site, clutch size tends to decline through the season and, in line with this, second clutches tend to be smaller than first clutches. Much research has focused on the evolution of clutch size in parids, and in general it appears that the female lays a number of eggs that is consistent with her "prediction" of what the pair will be able to raise in order to maximize the chances of chicks surviving and eventually being recruited into the breeding population.

The incidence of second clutches also varies greatly within and among species, although it seems that more *Poecile* species have been recorded as laying a second clutch than have species in other genera. Since proof of re-laying requires the female to be identified, however, knowledge of this is of necessity incomplete. Second clutches occur particularly in habitats in which prey animals exhibit a low but prolonged peak of availability, rather than a sudden short-term flush. This low, protracted peak in prey abundance is linked especially with evergreen woodlands, such as conifer woods, and so it is noteworthy that Coal Tits, which are strongly associated with conifer forest, may even lay a third clutch. Timing imposes the severest constraint on the birds' ability to rear a second brood, since the postnuptial moult, which commences with loss of the innermost primary, starts immediately after breeding; indeed, the males of many pairs will start to moult before the first or the only brood fledges. Genuine second clutches tend, therefore, to be laid by females which laid the first clutch early in the season.

Incubation usually commences upon clutch completion. With later clutches, however, it may start up to three days, or three eggs, before the last egg is laid, in order to reduce the time necessary for the whole breeding attempt. This results in hatching asynchrony, the last eggs hatching up to three days after the rest, which may also lead to the death of the last chicks. Incubation does not start suddenly, but it increases gradually, the fe-

male delivering a little heat to the clutch at night when she roosts on the nest, even from the first egg. Although this may not be enough to initiate significant embryonic development, it is detectable by the time when full incubation starts by the greater weight loss, through water loss, from the first eggs than from later ones. In Britain, the warmer spring weather in recent years has allowed Great Tits to lay eggs so much earlier that they can delay incubation after clutch completion in order to optimize the timing of the hatch in relation to the predicted caterpillar peak. As a consequence, hatching asynchrony and brood reduction have become less frequent in these populations. Generally, incubation is undertaken solely by the female, but there are two known exceptions to this, both involving *Parus* species. These are the White-winged Black Tit in Africa and the Black-lored Tit in Asia, the males of which share incubation, although few details are available. For the task of incubation, the female develops a brood patch through which to deliver heat, the clutch temperature being typically maintained above 30°C. The males of many parids feed the incubating female, at least for some of the time, while she is on the nest. Otherwise, a typical incubation schedule for the female is 50 minutes on the nest, followed by 10 minutes off the nest for feeding and sanitation, then a return to the nest, and so on.

The duration of the incubation period is unknown for half of all members of this family. The gap in knowledge is greatest for *Parus*, for which the incubation period is known for only six of the 23 species. Typical known incubation time, however, is 12–14 days, with a clear mode at 13 days. It may be longer for more northerly species, up to 18 days in the case of the Siberian and European Crested Tits. The comparatively long incubation time of parids is typical of hole-nesters, which tend to have safer nest-sites than do birds with open nests.

Hatching success of tits and chickadees is typically high, with often 85–100% success within clutches. There appears to be a slight tendency for first and last eggs to be more prone to hatch failure, and recent research indicates that male eggs, which in all other respects, such as size, shape and colour, are the same as female eggs, are more likely to perish before hatching. Using its egg tooth, the chick hatches by breaking the shell between the air-cell and the broadest part, where there is a band of thinner shell

The nestlings of the **Common Blue Tit** are raised mainly on tree-defoliating caterpillars, perhaps because of their high energy and water content. They are also provisioned with adult *Lepidoptera*, as this photograph attests. Powered by this diet, the nestlings grow rapidly, essentially doubling in weight in the first three days after hatching, then doubling again after six days, and again after ten days, by which time the eyes are open and the plumage is well developed. At high latitudes, large broods are the norm. Seven chicks are visible here, but it is perfectly usual for a Common Blue Tit to lay 13 eggs in northern Europe; clutches found in excess of 18 eggs will almost certainly have been laid by two females.

Parids nest in cavities as a defence against predation, but this risk is not entirely removed.

The nest contents are sometimes eaten by

mustelids, rodents, sciurids, snakes and woodpeckers

(Picidae). Predation tends to be greater at the chick

stage than at the egg stage, presumably because

predators are attracted by the noise and odour produced by chicks. One

way of reducing the smell is to remove droppings in

the form of faecal sacs, as demonstrated by this

**Common Blue Tit**. This tactic is also beneficial

because it improves nest hygiene and reduces the risk of attracting parasites.

which may have a ring of spots. Parid hatchlings are blind and naked, apart from a few wisps of fine down on the head. Immediately from hatching they beg for food, presenting the pale yellow mouth to the female. The brood is fed by both parents, although the male may play a greater role in this when the female has to brood the young, for example, especially during the first week when the chicks are not yet able to thermoregulate for themselves.

Co-operative breeding, whereby individuals other than the genetic parents help to raise the brood, has been noted, or strongly suspected, for *Baeolophus* species, such as the Bridled, Tufted and Black-crested Titmice, and for all African species for which details are available, namely the Southern Black Tit, Carp's Black Tit, and the Rufous-bellied, Grey and Ashy Tits, and it may be that most, if not all, African *Parus* breed co-operatively. The Ground Tit, too, is a co-operative breeder. For those species for which relevant studies have been made, helpers are found to be related to the primary pair, and are often the young from a previous brood of that pair. In the case of the Ground Tit, helpers, which are always male, are also more closely related to the primary pair than are randomly sampled males in the population. For all these species, the assistance provided by helpers in the raising of kin probably represents a better strategy than that of trying to find a mate and to breed independently in an environment in which nest-holes may be scarce and the species' density very low.

The nestlings grow very rapidly, essentially doubling in weight from the time of hatching (day 1) to day 3, then again to day 6, and again to day 10, by which time the eyes are open and the plumage is developing. By day 15, they reach or, indeed, may well have surpassed their parents' weight through the accumulation of body fat, as well as through the increase to full-grown body size; it is not uncommon for Great Tit chicks to fledge at a weight of 23 g, although their parents weigh 17–19 g. In order for the young to achieve this, the parents of larger broods have to deliver prey at a prodigious rate of up to one caterpillar every 2–3 minutes, parids usually delivering only one prey item at a time to the nest; initially they catch smaller prey closer to the nest,

and then gradually larger prey as they forage farther from the nest. This achievement is all the more remarkable because in this brief period of time the adults not only find and select prey, but also process it for the brood (see Food and Feeding). In addition to the main prey, the parents bring minerals and nutrients such as grit, and snail shell to provide calcium for growing bones. When calcium is scarce, deformities, especially of the legs, have been noted, as with, for example, the Great Tit and the Mountain Chickadee. As well as bringing food to the brood, the parents remove faecal sacs, dropping these well away from the nest so as not to attract predators. Nest predators include mustelids, rodents, sciurids, snakes and woodpeckers (Picidae), and predation at the chick stage tends to be greater than that at the egg stage, presumably because predators are attracted by the chicks' calls.

As with incubation, the length of the nestling period is unknown for half of all parid species. For those for which it is known, it is generally 16–22 days, with a mode of around 19 days. The variation probably reflects food availability and, hence, the rate at which the chicks develop. The Ground Tit appears to be an exception in having a prolonged nestling period, believed to be up to 25 days. Parid chicks are more or less fully developed and well feathered at fledging, although the wings, the tail and the bill may be only about 85–90% of their final lengths. As the fledging weight of chicks is a strong indicator of food availability, chicks of early broods tend to be heavier than those of later broods, and chicks in small broods tend to be heavier than those in large broods. The weight at fledging is a strong determinant of a chick's probability of surviving not only the first few days, but also the longer period leading to subsequent recruitment into the breeding population.

The "decision" on when the chicks leave the nest is made by the parents, which have to induce the young out by ceasing to feed them directly but, instead, presenting food tantalizingly from outside the nest-hole. The sequence of departure is not random, the second heaviest often being the first to leave in the case of Great Tit broods, but once a few have left, and are being fed outside the nest, the rest must follow or, if they do not, starve.

The timing of fledging is determined by a shift in adult behaviour in the **Black-capped Chickadee**, and all other parids. The adults start to present food items outside the nest-hole, tempting the hungry nestlings to leap from the cavity one by one to a nearby branch, where they are fed. After fledging, the young are provisioned by both parents for a further 21–28 days, although they can feed themselves within seven days of fledging. After a month on the natal territory the young disperse over short distances.

Animals Animals]

The young tits are dependent on one parent, usually the male, or on both parents for a period of time after fledging, and, among co-operative breeders, helpers have also been recorded as continuing to feed the brood-members after they have left the nest. The length of the period of dependency varies widely from one species to another. Although it is unknown for most members of this family, the 17 parids for which it has been documented show a pattern in which pair-territorial and group-territorial species tend to have much longer periods of dependency than do the flocking species, the high-density populations of which place a premium on the achieving of independence. Examples of fledgling dependency in the former groups are 21–45 days for *Baeolophus* titmice, 50 days for Southern Black Tits, up to 60 days for Carolina Chickadees and 80 days for Varied Tits, whereas illustrations of dependency among flocking species include usually 6–8 days for Great Tits and about 7 days for Common Blue Tits. When comparing these strategies of pair-/group-territorial and flocking species, and when comparing breeding strategies within flocking species such as the Great Tit in years of high and low breeding density, a trade-off emerges. This is between the strategy of having few, high-quality fledglings, such as in a high-density "competitive" situation, and that of flooding the woods with large numbers of poorer-quality young, as in the low-density, low-competition situation.

## Movements

Although Paridae contains some of the most sedentary of passerine birds, particularly among the pair-territorial and group-territorial *Poecile* species, and although none can truly be classified as migratory, three well-defined recurrent patterns of movement can be identified within the family. These are post-juvenile dispersal, altitudinal movements, and eruptions. In the last two cases, the movements are clearly a response to a declining food supply and worsening autumn or winter weather conditions. Post-juvenile dispersal is also driven partly by the search for food, after the young become independent of their parents, but it is also governed by the future need of juveniles to find territories of their own.

Elevational movements, such as the descent of the Himalayan-dwelling Black-breasted and Rufous-vented Tits to lower levels

in winter, may appear to be largely predictable. Nevertheless, even these species remain above 2000 m, and these are only partial migrations in that it is not the entire populations that move, many individuals remaining at very high altitude throughout the winter months. In many partially migratory passerine species, the individuals that do not migrate are adults staying on territory; the migrants are first-years, and this could be seen as an extension of post-juvenile dispersal, which may be the case with these altitudinally migrating tits.

Altitudinal migration has been reported for no fewer than nine *Poecile* species, namely the Sombre and Willow Tits, the Black-capped, Mountain, Mexican, Boreal and Chestnut-backed Chickadees, and the White-browed and Varied Tits. It is recorded also for four *Periparus* species, the Black-breasted, Rufous-vented, Spot-winged and Coal Tits, for one *Lophophanes*, the Grey-crested Tit, for one *Baeolophus*, the Black-crested Titmouse, for four *Parus* tits, the Great, Green-backed, Black-lored and Yellow-cheeked Tits, and for two *Cyanistes* species, the Common Blue and Azure Tits. Of these twelve species outside the genus *Poecile*, nine migrate altitudinally within their Himalayan ranges at very high elevation, whereas none of the *Poecile* species listed occurs in the Himalayas, and the *Poecile* movements tend to occur across a much shorter distance than do those of many of the other species. One may speculate that, while the altitudinal migration by all these species is only partial, some individuals, probably adults, remaining all year on the breeding grounds, the social organization of *Poecile*, with the need to join a group territory, may place a greater stress on juveniles of this genus than is placed on the juveniles of *Periparus*, *Parus* and *Cyanistes* by a flocking social organization when at similar altitude.

Although social organization may act to ameliorate the effects of food shortage on starvation risk and, hence, on movements, ultimately it is the availability of food, rather than social organization, that determines these movements. Such effects are clearly evident at a local level when, for example, Coal Tits are reported as visiting feeders in British gardens at significantly higher densities in years of a poor beech crop than when the crop is abundant, or it is noted that European Crested Tits moved much farther after a storm felled most trees in their Belgian territory. It is all the more evident, however, on the national or international scale in the form of mass-exoduses, or eruptions. In north and east Europe, eruptions of Great Tits, Common Blue Tits and, to a

After fledging, young tits remain dependent on one parent, usually the male, or on both parents. The duration of this period of dependency varies widely in the 17 species for which it is known. The period lasts longer in pair-territorial and group-territorial species than it does in flocking species. Fledglings are dependent for 21–45 days in *Baeolophus titmice*, and 35–80 days in *Poecile* tits, for example, while they are only dependent for 6–8 days in the Great Tit (*Parus major*) and seven days in the **Common Blue Tit**. It seems likely that the high-density populations of the latter species place a high premium on achieving independence.

[*Cyanistes caeruleus*

Animals Animals]

lesser extent, Coal Tits occur, when individuals move south and west across the rising temperature gradient, in years of beech-crop failure or very heavy snowfall. Some of these tits reach as far west as Britain, although, with the first two species, that tendency has declined since the mid-1970s, presumably because of rising winter temperatures and a greater propensity for humans to feed birds in winter. Eruptions arising from failure of seed crops, primarily beech mast or pine seed, is reported for three *Poecile* species, the Willow Tit and the Boreal and Chestnut-backed Chickadees, for one *Periparus*, the Coal Tit, for one *Baeolophus*, the Tufted Titmouse, for one *Parus*, the Great Tit, and for two *Cyanistes* species, the Common Blue and Azure Tits, indicating that fleeing from food shortage is a widespread response in Paridae. In some cases, irruption by a species into an area beyond its normal range can bring it into competition with congeners. Such a situation occurs with the Azure Tit, which, when forced west into the range of its smaller sibling species, the Common Blue Tit, is socially subordinate to it. This probably reflects site-related dominance, since local birds are normally socially dominant over immigrant or transient individuals, but it may relate also to the Azure Tit's weaker plumage badges, referred to earlier (see General Habits), which may signal its subordinate rank to the Common Blue Tit; dominance status is as much in the eye of the beholder as in the heart of the actor. Site-related dominance is an important driver of social organization in flocking parids, but less so in pair-territorial and group-territorial species such as the Black-capped Chickadee, although, for the Willow Tit, "prior residency" is important in determining dominance hierarchies. In flocking parids, it determines that an individual may behave as dominant in its own territory or home range, but as subordinate when away from that range. It was first described by an amateur ornithologist, A. Brian, in relation to the Great Tit, and, although the description of its occurrence related to the breeding season and probably, therefore, referred to territorial individuals, it is important also in winter, and especially at feeders. Although flocking species display greater fluidity in their flock-joining behaviour, they tend to establish a regular "beat" during a given winter. This is shown by analysis of ringing recoveries of British Great and Common Blue Tits, which demonstrates a significantly stronger tendency to travel distances of more than 20 km from one winter to another than they do within a single winter period.

Despite the observation of between-winter movements of more than 20 km made by adults, such lengthy displacements are exceptional, making up far less than 1% of all movements recorded in ringing studies. In general, parids are most mobile in the period prior to territory establishment. The main times of the year during which movements seem to be most significant are, first, the exploratory-dispersal period of juveniles after they become independent of their parents, which may extend through the summer with the coalescing of juvenile flocks, and, secondly, the late winter

Parids are among the most popular of birds in the Northern Hemisphere. Their fame and familiarity rests not on their beauty, although they are undeniably pretty, but on their confidence and tameness. Indeed, there are plenty of beautiful birds that are too rare or shy to make much of an impression on the general public. In particular, tits are more than willing to accept handouts of food, and to occupy nestboxes. These are key factors in allowing many parids, including the **Carolina Chickadee**, to survive and thrive in cities and gardens.

During the European winter, the **Great Tit** may swarm around peanut feeders in suburban gardens. Provisioning by humans is known to improve the tits' survival prospects significantly. It allows them to overwinter in suboptimal habitats, and it increases their population density around gardens or in suburban settings. There has thus been an extraordinarily positive feedback between tits and humans in terms of quality of life. The more tits there are in nestboxes and around feeders, the more pleasure humans derive from watching them, and thus the more humans there are putting out nestboxes and feeders, which leads to more increases in the populations of tits around human settlements.

and early spring, when the need to establish a territory becomes most acute. There has been much debate over the importance of, on the one hand, genetically inherited tendencies, with the question of whether some birds possess a genetic predisposition to disperse, and, on the other, the role of competition in driving dispersal. Detailed investigations of Great Tit behaviour and movements, especially in the Netherlands, Belgium and Britain, indicate that, although broodmates tend to move similar distances and in similar directions to reach their first breeding sites, this is because they tend to move together, rather than because they are genetically predisposed to move for a certain distance or in a particular direction. Genes do, however, appear to be involved in determining what has been termed the bird's "personality", its intensity of exploratory behaviour in novel environments, and this has a bearing on dispersal, since fast-exploring parents have offspring that disperse farther, immigrants tend to be faster explorers than locally bred individuals, and post-fledging movements tend to be greater for fast-exploring females than for slow-exploring ones.

In general, studies of dispersal have found that female parids move farther between the natal site and the site of first breeding than do males, although most individuals, of both sexes, settle within 3 km of the natal site. The apparently greater mobility of females may reflect their lesser attachment to territory, establishment of which often starts in the autumn for flocking species, but it may be linked also with their lower social dominance, since reduced access to food is likely to cause individuals to move more. This may be reflected further in the greater overwinter mortality reported for females, compared with males, of several species, examples being the Great Tit and the Willow Tit, but not the Coal Tit, although it may equally represent a cost of reproduction. For example, Willow Tit females that do not breed in their first breeding season are more likely to survive to the next year.

That social dominance, related to prior residence, plays a part in driving dispersal is suggested by a number of observations and experiments. In some Great Tit populations, such as in Belgium, later-fledged young are more likely to emigrate than are earlier-fledged young. This has not been observed in all populations, as demonstrated by studies at, for example, Wytham, in southern England, but it might reflect the size and configuration of woodland habitat patches rather than any genetic or social difference between the populations themselves. In both of these aforemen-

tioned populations, it has been noted that later-fledged young are more likely to have retained the juvenile greater coverts after the post-juvenile moult, which occurs during that first summer, than are earlier-fledged young. Females of the Great, Common Blue and Coal Tits are also more likely to retain juvenile greater coverts than are males. There is evidence that incomplete moult of this nature reflects nutritional stress at the time of moult more than it does any genetic predisposition, therefore suggesting that these later young are more stressed than are the earlier young. For example, juvenile Great Tits with retained greater coverts tend to be in poorer condition in winter. It is likely that what makes the difference between early-fledged and later-fledged young is the greater competition imposed on later young at their most vulnerable time by earlier young, which have already had time to establish themselves. There is no doubt that the greatest mortality experienced by juveniles occurs during these first few days or weeks after fledging, and especially around the time of independence. Furthermore, it was shown many years ago that the survival rate of second-brood young Great Tits was significantly enhanced if chicks from first broods were removed from the area.

Finally, in relation to social pressures, it is perhaps no surprise to find that it is immatures that are the first to discover and exploit new resources. They are also the first to risk returning to feed at a feeder after a predator has left. It was probably a juvenile Common Blue Tit that first discovered in England, in 1921, that rich pickings lay at the top of a milk bottle if it could peck through the foil top; Great Tits learned this habit later.

### *Relationship with Man*

Parids have a strong association with humans in the Northern Hemisphere, where they are among the most familiar of all birds. This is not only because of their tameness and willingness to accept food and nestboxes provided by people, but also because their acrobatic antics are among the most engaging of those seen in the bird world. Tits and chickadees feature prominently, therefore, in European and native North American folklore.

The name "titmouse" is first recorded in English in 1325, as *titmose*, from the Middle English word *tit* or the Icelandic *titr*, meaning "small", and *mase*, an Old English word meaning "a small

The **Stripe-breasted Tit** is a restricted-range species present in the Albertine Rift Mountains Endemic Bird Area, a region that is poorly known and difficult to visit outside south-west Uganda. This species is common throughout the montane zone, mainly between 1800 m and 3400 m, in forest, bamboo-dominated undergrowth, and tree-heath. It survives in good numbers, even in fairly degraded forests, but its small range means that continued clearance of suitable habitat might place it at risk in the future. Females can be distinguished by their slightly browner heads and breast stripes; the individual pictured here is an adult male.

[*Parus fasciiventer*

Dean]

bird". Hence, *titmose* is literally a small, small bird. This form is last recorded in 1570, by which time the form "titmouse" had come into use, possibly encouraged by the mouse-like behaviour of the familiar parids with their quick, flitting actions. Incidentally, since the "mouse" part of the word here is a corruption of the Middle English *mose*, its plural should technically be "titmouses", rather than "titmice", although this presents an "uncomfortable" sound to the modern English-speaker. "Titmouse" remained the common usage in both British and US English until the twentieth century, during which the abbreviated form "tit" became commoner for informal use, and for formal use from the 1950s, in Britain, while "titmouse" remained in use for the *Baeolophus* species of the USA. The North American name of "chickadee" obviously alludes to the calls of the Nearctic *Poecile* species; it is not clear whether the word was used first by Europeans, but it was first recorded in English by H. D. Thoreau, in 1838.

The significance of parids to humans is indicated by their appearance in traditional folklore. For the native North Americans, who traditionally stressed the close relationships between humans and nature, the chickadee often had special significance. Chickadees frequently occurred in the dream beliefs of the Pueblo Indians, although the chickadee often offered false gifts to the dreamer. These dreams were induced during fasting, and the coming of the chickadee in children's dreams became an accepted part of the vision-generating fast. In other Indian cultures, the chickadee was more valued. The Indian tracker Tom Brown, Jr, said: "We learned to be patient observers like the owl. We learned cleverness from the crow, and courage from the jay, who will attack an owl ten times its size to drive it off its territory. But above all of them ranked the chickadee because of its indomitable energy for life." In reporting his childhood dreams, the Chief of the Crow Nation, Plenty Coup, stated that he "was made aware of the tiny chickadee who was least in strength but strongest of mind among his kind. This little speck of a bird was willing to work to gain wisdom, and he was an exceptional listener. Nothing escaped his ears, which he had sharpened by constant use...". Furthermore, he said that the chickadee taught him "Develop your body, but do not neglect your mind. It is the mind that leads a man to power, not strength of body... We must be wise like the chickadee...". One may speculate that, among native North American cultures, respect for the chickadee's wisdom arose from

observation of the birds as they hoarded food for the winter. Chickadees can also be prominent in European American culture; for example, the Black-capped Chickadee was formally adopted as the state bird by the Massachusetts Legislature in 1941.

Folk traditions derived from parids exist also in the Old World. In Finland, the song "Ti-Ti-Tyy Jenka" was said by its composer, Orvokki Ramsi, to have been inspired by the song of the "European titmouse", and an old Estonian proverb states *Paremb tiganõ peoh ku mõtus ossa pääl*, meaning "Better a titmouse in the hand than a wood-grouse on a branch". In east Asia, the importance of the Varied Tit as a cagebird in Korea is underlined by its depiction on a set of stamps. Similar anthropological evidence for hu-

One poorly known parid is endemic to the Central Sichuan Mountains Endemic Bird Area: the **Rusty-breasted Tit**. It is generally found between 2135 m and 3400 m in mature mixed forest, usually with a component of spruce, fir, pine, birch, poplar, alder and oak, and an understorey of bamboo. It is a restricted-range species, but is not globally threatened. Its population is fairly large, though given the small range, and the accelerating deforestation occurring within it, it may decline in future. The situation requires monitoring.

The **Yellow Tit** is restricted to Taiwan, breeding in temperate primary broadleaf forests at 1000–2500 m, and descending to lower altitudes in winter. It is generally uncommon, but perhaps more numerous in the hilly south and west of the island. The large-scale destruction of suitable forests is causing a decline, especially as the species seems to be out-competed in marginal habitats by the Green-backed Tit (*Parus monticolus*). Numbers are further reduced by illegal trapping for the cagebird trade. The Yellow Tit is classified as a Near-threatened species present in the Taiwan Endemic Bird Area.

man familiarity with parids comes from the number of alternative names that exist for some of the species. These may reflect an association in the human mind between the bird and the land, such as the old English name of "Ox-eye" for the Great Tit, or they may demonstrate familiarity with a species' behaviour, as in the English name "Billy-biter" for the Common Blue Tit, other names for which include "Tom Tit", "Blue Cap" and "Nun", or they may allude to the species' vocal character, as with the name of "Saw-sharpener" for the Great Tit. The importance of the Common Blue Tit to city people is nicely illustrated by the results of a recent competition held by the BBC, in London, England, to find a new name for the species. With more than 500 votes cast, respondents suggested some 40 different names, including "City Blue", "Fidget", "Bluey", "Tweety" and "Mrs Blue", but the winner, with 53% of the vote, was "Wee Mum".

The human fondness for parids is partly a result of the willingness of tits and chickadees to come for food put out at feeders and on birdtables (see Food and Feeding), but it is also strongly linked with their willingness to use artificial nestboxes. The interest of many young birdwatchers must have been awakened by the intense activity of a pair of Common Blue Tits or Black-capped Chickadees at a nestbox. Had this habit done no more than raise people's interest in birds and the natural world more widely, it would have served both humans and the birds well, but the attraction of, especially, Great Tits to nestboxes has provided the sciences of ornithology and ecology with the most powerful insights into the workings of natural populations. The ultimate reasons for the intense interest in Great Tits is surely one of convenience, but much of what is known about the evolution of clutch size, of density-dependent population regulation, of the timing of reproduction, and of the effect of food supply on population dynamics and on other demographic processes, to name but a few aspects of avian ecology, has its roots in a few long-running and detailed nestbox-based studies of the Great Tit, some of these having started more than 60 years ago, especially in the Netherlands and UK. The initiation of these studies was motivated in about 1900 by the desire to control caterpillar pests in orchards. Conservation science owes much to this species' interest in peanuts and nestboxes.

### Status and Conservation

In conjunction with the behavioural flexibility of parids in general, and their adaptability to anthropogenic change, only four of the 56 species are listed by BirdLife International in any category

other than that of Least Concern. All four occur in the Oriental Region. One of these, the White-naped Tit of India, is globally threatened, being classified as Vulnerable, while the other three, the Palawan Tit, the Yellow Tit and the White-fronted Tit, are listed as Near-threatened. The threats that these species face vary. The White-naped Tit is threatened chiefly by loss, fragmentation or degradation of its thornbush habitat; it has recently suffered a rapid population decline. The Palawan and White-fronted Tits, both restricted to the Philippines and both uncommon, are at risk because of the suspected dependency by their localized populations on habitat that could be threatened. The last of the four species, the Yellow Tit, although its habitat appears to be secure, occurs at low density and may be threatened by the trapping of wild birds for export. Incidentally, some populations of the Varied Tit in east Asia may likewise be at risk through trapping for the cagebird trade. Given the widespread use made of nestboxes by other parid species, one wonders whether some of these Oriental species could perhaps be helped by the provision of such boxes. Away from the Oriental Region, in Africa, the Red-throated Tit may also be considered to be potentially at risk because of habitat degradation, and the Miombo Tit is potentially vulnerable because of its specific habitat requirements.

Although not threatened globally, a number of other species contain populations that may not be secure. Regional forest clearance gives cause for concern for populations of the Bridled Titmouse along the Gila and lower Salt Rivers, in south USA, the Mexican Chickadee in central Mexico, the Siberian Tit in Norway and Finland, the Dusky Tit in western Angola, the Stripe-breasted Tit in the Albertine Rift, in central Africa, the Yellow-bellied Tit in China, and the Sultan Tit in the western Himalayas and northern India; the last-named is no longer found in Bangladesh. In addition, the Rusty-breasted Tit, a restricted-range species found in the mountains of central Sichuan, in China, may be more at risk than is formally recognized.

Other populations considered to be at risk include the Marsh Tit and Willow Tit in Britain, where both species have declined over the last 30 years, in the latter case dramatically rapidly, the Willow Tit having almost disappeared from a number of southern counties where it was formerly common. The reasons for these declines are not clear, but they possibly include increasing competition with Common Blue Tits, both for nest-holes and when foraging in winter, and a reduction in the availability of low nest-sites because of browsing pressure from an increasing deer population. In a very few cases, entire subspecies are at risk. These include the race *degener* of the Canary Blue Tit on Fuerteventura

The **Palawan Tit** is restricted to the Palawan Endemic Bird Area, centred on the Philippine island of Palawan. It occurs in the lowland and submontane zones, in a range of forest types, including primary forest, secondary forest, and the margins of swamps and cultivation. This ecological flexibility suggests that it is not immediately threatened with extinction. However, intensive logging is escalating within its restricted range, and a fairly rapid population decline is likely. The species is therefore classified as **Near-threatened**.

and Lanzarote, which suffers poor breeding success and may be susceptible to increasing desertification of these islands, and the Borodino Islands race *orii* of the Varied Tit, now presumed extinct following widespread habitat loss.

At the other extreme, a number of parids have extended their range in recent years. These include the Black-capped Chickadee in the eastern USA; the Sombre Tit in southern Europe, possibly responding to the warming climate; the Great Tit north of the Arctic Circle, including a population maintained in winter by human provisioning; and the Yellow-cheeked Tit in southern Asia, where its range now includes Hong Kong.

Globally, the Paridae exemplify the need for detailed data for the purpose of conservation assessments. As indicated above, the status of several African species may be more precarious than is currently recognized, because of the lack of census data indicating changes over time. Indeed, to the Red-throated and Miombo Tits we could perhaps add the White-bellied Tit, whose range appears to have contracted in parts of Kenya, and the White-backed Black Tit, which has not been recorded in Eritrea for 50 years.

The **White-naped Tit** is endemic to India, occurring mainly in the arid north-eastern states of Gujarat and Rajasthan, but also in the southern states of Karnataka, Kerala and Tamil Nadu. In the south it is rare, and even in the stronghold of Kutch (Gujarat) it is sparsely distributed. It usually inhabits Acacia thorn-scrub, which has been degraded and fragmented through clearance for agriculture, industry, firewood, charcoal, and other human uses. The total population size is therefore assumed to be small and declining, and the species is listed as **Vulnerable**.

Genus *POECILE* Kaup, 1829

## 1. Sombre Tit

*Poecile lugubris*

**French:** Mésange lugubre      **German:** Balkanmeise      **Spanish:** Carbonero Lúgubre  
**Other common names:** Caspian/Elburz Tit (*hyrcanus*)

**Taxonomy.** *Parus lugubris* Temminck, 1820, Dalmatia and Hungary.

Until recently present genus normally subsumed into a broad *Parus*, and many authors still prefer that treatment. Genus normally treated as feminine, but no evidence in original description or elsewhere justifies this, so genus is masculine by default. Has been considered conspecific with *P. davidi*. Race *hyrcanus* has been treated as a separate species on basis of differences in voice and breeding behaviour and apparent absence of intergradation with neighbouring *dubius* and *anatoliae*; close to former race in structure and plumage and to latter in plumage, but vocal characters and breeding biology similar to those of *P. montanus* (especially of “*songarus* group”); further study required. Geographical variation largely clinal, size decreasing from N to S, crown and bib darker from S to N & E, and underparts increasingly paler from W to E; described race *splendens* (from E Romania and E Bulgaria) somewhat larger and paler than nominate, but considered better synonymized with it. Six subspecies recognized.

**Subspecies and Distribution.**

*P. l. lugubris* (Temminck, 1820) – extreme NW Croatia S to Albania, and C & S Romania S to E Bulgaria and N Greece, also Crete.

*P. l. lugens* (C. L. Brehm, 1855) – C & S Greece.

*P. l. anatoliae* (E. J. O. Hartert, 1905) – Asia Minor, W Georgia, extreme S Armenia and Levant (S to N Israel).

*P. l. hyrcanus* Zarudny & Loudon, 1905 – SE Azerbaijan and N Iran (Elburz Mts).

*P. l. dubius* (Hellmayr, 1901) – W Iran.

*P. l. kirmanensis* (Koelz, 1950) – SE Iran (Kerman).

**Descriptive notes.** 14–15 cm; 16–19 g. Large, large-billed, grey-brown tit with blackish cap and bib. Male nominate race has upper lores and crown to nape blackish-brown to dark sooty brown, lower lores, cheek and ear-coverts white, becoming buffish on neck side; upperparts mostly dull ash-brown, slightly greyer on uppertail-coverts; tail grey-brown, tinged olive-grey, fine whitish fringes on outermost feathers; upperwing-coverts as upperparts, but greater coverts fringed buffish or paler, alula dark grey to blackish; flight-feathers dark grey, narrowly fringed pale greyish-buff, tertials similar but more broadly fringed

greyish to buffish-white; chin, lower cheek and throat sooty brown, forming bib (with lower border poorly defined); underparts whitish, washed buffish on breast and flanks (duller off-white and greyish on flanks when worn); plumage greyer above and whiter below in E of range (“*splendens*”); iris brown to dark brown; bill dark grey to blackish-horn, with paler or greyish cutting edges of upper mandible; legs dark grey to bluish-slate. Differs from *P. palustris* mainly in larger size, more robust bill, dull blackish-brown (not glossy black) cap, greyer-tinged brown upperparts, and more black on bib and throat. Female is very like male, but crown variable from blackish-brown (as male) to dark chocolate-brown, bib browner, underparts duller or washed greyer. Juvenile is similar to female, but crown brown or dark grey-brown (as upperparts), whitish cheeks washed buffish or brownish, greater coverts prominently tipped whitish, bib smaller and finely tipped greyish-buff, underparts washed buffish or dingy, to off-white on undertail. Racial variation moderate, but also considerable individual variation: *lugens* is smaller than nominate, male has grey-tinged dark sooty-brown crown and bib, female paler or greyer-brown; *anatoliae* is as nominate, but crown and bib black (male) or blackish to sooty brown (female) and clearly defined at rear, mantle and scapulars dark olive-brown, underparts whiter, flanks washed cinnamon in fresh plumage; *dubius* has slightly longer and more slender bill than other races, crown and bib velvety black (or tinged brown on female), upperparts paler or sandy-grey, underparts whitish with creamy wash; *kirmanensis* is poorly defined, very similar to previous but upperparts slightly darker and browner; *hyrcanus* is slightly smaller and darker than others, with shorter tail and relatively large bill, has extensive dark chestnut-brown cap to nape and upper mantle, darker brown upperparts (mantle may be tinged pinkish), tertials lack broad pale edges, bib darker than crown (slightly more extensive in worn plumage) and lower edge poorly defined, underparts washed rusty or pinkish-buff in fresh plumage (whiter when worn). VOICE. Call notes include thin or nasal “si” or “zee” as contact, or extended into longer and slightly declining cadence of “si-si-si-si-si-si”, or may conclude with short chattering “ttrrrr”, harsher “chit” also given in bursts of sharper chattering notes, “chit-cht-cht-cht-cht”, and may be introduced by thin “si”; other combinations of calls include “tsi-tsi-tsi-zee”, “tsi-tsi-tsi-tsi-tsi-tsi-ttrrr”, or “sirrah”, “sit-sit-sirrah” and “sisi...cheerrrrrr”, “sip” or “snipp” in flight; alarm call a loud, prolonged and hurried chattering “ttrrrrrr” or “chrrrrrr” like that of sparrow (*Passer*), sometimes preceded by slower insect-like “si si” or “zi zi ttrrrr” or “tiz-ze-ze-ze-ze-ze” (which may be given in isolation from chattering note); during courtship, begging call of female “che-ka-di-che-ka-di-tsi-tsi”, and soft “tsi-tsi-tsi” by both birds during mating; female on nest gives threatening snake-like hissing; alarm call of race *hyrcanus* a short, nasal “chev” or “tshef” repeated several times or more prolonged. Song, from top of tall tree, given with varying pitch or emphasis usually for short period prior to egg-laying, a series of “tea-cher”-like phrases, recalling songs of both *Parus major* and *Periparus ater*; also, low-pitched, hard “chip-chip-chip” repeated a dozen or more times, shorter “cheeu-cheuu-cheuu” or stident or slightly gruff or buzzing “chiz-ze, chiz-ze”, or variations e.g. “tu-ch-zai, tu-ch-zai, tu-ch-zai”; song of *hyrcanus* a clear and slightly attenuated “tiu” repeated up to five times.

**Habitat.** Inhabits dry maquis areas of scattered trees and bushes, including olive (*Olea*) groves, wild plum (*Prunus*) orchards and other fruit trees, e.g. wild pear (*Pyrus amygdaliformis*) and vineyards, also parkland areas of open oak (*Quercus*) forests including scrub oak, beech (*Fagus*), wil-

lows (*Salix*) and poplars (*Populus*); also conifers, particularly spruce (*Picea*) and cedars (*Cedrus*), especially in areas of rocky limestone hills. From sea-level around Mediterranean, up to 2300 m in Turkey and N Iran (Elburz Range); in N Israel breeds at 750–1700 m; in Azerbaijan not found below c. 550 m.

**Food and Feeding.** Small invertebrates and larvae, including beetles (Coleoptera), grasshoppers (Orthoptera), bugs (Hemiptera), flies (Diptera), bees and wasps (Hymenoptera), ants (Formicidae), damselflies (Odonata), lacewings (Neuroptera), moths (Lepidoptera), spiders (Araneae), woodlice (Isopoda) and snails (Gastropoda); also seeds, mainly of Leguminosae; in captivity, frequently stores food. Usually in pairs in breeding season; often in small groups in autumn and winter, occasionally solitary in winter. Shy, unobtrusive. Forages in lower branches of trees and shrubs, occasionally briefly on ground, but usually returns to bush or branches of tree with food items; in S Caucasus forages mainly in canopy of deciduous trees. Active but generally less acrobatic or agile than other tits. Climbs tree trunks like a nuthatch (Sittidae), and occasionally pursues insects in flight in manner of flycatcher (Muscicapidae). Food items held in foot and hammered open with bill, also seeds wedged in bark before being opened; seedheads, including those of herbs, torn open in manner of a finch (Fringillidae).

**Breeding.** Season Mar to early Aug; mostly single-brooded but two broods not uncommon, and double-brooding frequent in Israel. Monogamous; territorial, during breeding most time spent within 150 m of nest, territorial conflicts rare. Male courtship-feeding female, display includes wing-shivering and begging calls. Nest, built by female, a cup of wool, plant material, bark strips, animal hair and feathers, placed up to 7 m from ground in hole in tree, often in rotting wood in fruit tree (some evidence that race *hyrcanus* excavates hole), also among rocks on bank; will use nestbox; territory in oak woodland in Croatia 300–400 m in diameter. Clutch 5–7 eggs; incubation by female, period 12–14 days; both sexes feed chicks, nestling period 17–22 days; defends nest from predatory ants *Liometopum microcephalum* in oaks in Balkans by collecting those passing near nest entrance and crushing them against bark (which apparently causes alarm pheromone to be released by ants, deterring others from entering hole).

**Movements.** Resident, but some evidence of altitudinal movements in Zagros Mts (Iran) and N Israel; some apparent immigration from Lebanon and Syria into N Israel, where commoner in winter down to 600 m on Mt Hermon and Golan Heights; also wanders in autumn and winter to C Turkey and has occurred NE Iraq. Vagrant in N Italy.

**Status and Conservation.** Not globally threatened. Generally uncommon or locally common. Fairly common and widespread in Greece and W Turkey (less common inland), absent from Ionian islands except Corfu, also breeds on Lesbos, Samos and Kythira; rare on Crete; in Iran, scarce in NW but common in Zagros Mts of W & S; rare or sporadic throughout Caucasus; very scarce in Lebanon; locally common in N Israel. European breeding population 100,000–500,000 pairs; largest numbers in Bulgaria, although there has recently been a significant decline. Has recently extended range N in Romania (into Transylvania). Breeding densities of 9–10 pairs along 7-km stretch of sparse montane juniper (*Juniperus*) forest in Transcaucasia and 5–6 pairs along 4-km transect; in S Azerbaijan, pairs usually 0.5–2 km apart.

**Bibliography.** Cramp & Perrins (1993), Deshayes & Praz (1978), Eck (1980), Flint *et al.* (1984), Gill *et al.* (2005), Hagemeyer & Blair (1997), Handrinos & Akriotis (1997), Harrap & Quinn (1996), Harrison (1982), Hartert (1905, 1921), Hollom *et al.* (1988), Hüb & Elchécopar (1970), Löhrl (1966), Paludan (1938), Porter *et al.* (1996), Scott *et al.* (1975), Shirihai (1996), Svensson *et al.* (1999), Vaurie (1959).

## 2. Marsh Tit

*Poecile palustris*

**French:** Mésange nonnette      **German:** Sumpfmieise      **Spanish:** Carbonero Palustre  
**Other common names:** Eurasian Marsh-tit (*palustris*); Asian Marsh-tit (*brevirostris*); Black-bibbed/Chinese/Burmese Marsh-tit (*hypermelaeus*)

**Taxonomy.** *Parus palustris* Linnaeus, 1758, Europe = Sweden.

Until recently present genus normally subsumed into a broad *Parus*, and many authors still prefer that treatment. Genus normally treated as feminine, but no evidence in original description or elsewhere justifies this, so genus is masculine by default. Has hybridized with *P. montanus* and *Parus major*. Race *hypermelaeus* sometimes considered a separate species; also, *brevirostris* (with other E Palearctic forms) might represent a further species, though genetically not apparently very different. Race *kabardensis* has in the past been referred to by older name of *brandtii*, but type specimen of latter now lost and, since written description seems incompatible with present species, that name is regarded as indeterminate. Many races described, but most geographical variation clinal, with e.g. decreasing size and increasing intensity of upperpart colour from E to W; also, races intergrade widely, and *stagnatilis* and *kabardensis* sometimes included within nominate, and *jeholicus* sometimes merged with *hellmayri*. Other proposed races are *altaicus* (from Altai and W Sayan Mts) and *crassirostris* (SE Russia, NE China and Korea), both synonymized with *brevirostris*; as extreme view, species has been considered possibly monotypic, with high degree of variation within populations. Further research and review required, particularly of relationship between *hellmayri* and *hypermelaeus*. Eleven subspecies currently recognized.

**Subspecies and Distribution.**

*P. p. dresseri* (Stejneger, 1886) – S Britain (C & S England, Wales) and W France.

*P. p. palustris* (Linnaeus, 1758) – N & C Europe from S Scandinavia S to N Iberia, E to C Poland, W Balkans and Greece.

*P. p. italicus* (Tschusi & Hellmayr, 1900) – French Alps, Italy and Sicily.

*P. p. stagnatilis* (C. L. Brehm, 1855) – E Europe E to S Urals and NW Turkey.

*P. p. kabardensis* (Buturlin, 1929) – Caucasus and NE Turkey.

*P. p. brevirostris* Taczanowski, 1872 – SC & SE Siberia, N Mongolia, NE China (W & N Manchuria, Liaoning) and N Korea.

*P. p. jeholicus* (O. Kleinschmidt & Weigold, 1922) – NE China (N Hebei).

*P. p. hellmayri* Bianchi, 1902 – E China (Hebei S to Shandong and Jiangsu) and S Korea.

*P. p. hypermelaeus* Berezowski & Bianchi, 1891 – NC & S China (S Gansu & SW Shaanxi, C Hubei, and SW Sichuan S to NE Yunnan and NW Guizhou) and W Myanmar.

*P. p. ernsti* (Yamashina, 1933) – Sakhalin I.

*P. p. hensoni* (Stejneger, 1892) – S Kuril Is and N Japan (Hokkaido).

**Descriptive notes.** 11–12 cm; 8.9–15 g. Medium-sized, glossy black-capped, brown-backed tit with small blackish bib. Nominative race has forehead, crown and crown side (down to lower level of eye) to nape black, crown feathers glossy; upperparts, including upperwing-coverts, dull buffish-

**Food and Feeding.** Largely small invertebrates, including flies (Diptera), bugs (Hemiptera), stoneflies (Plecoptera), caddis flies (Trichoptera), bees and wasps (Hymenoptera), beetles (Coleoptera) springtails (Collembola), aphids (Aphidoidea), lacewings (Neuroptera), moths (Lepidoptera), ants (Formicidae), mites (Acari), spiders (Araneae), and small snails and slugs (Gastropoda). Also much vegetable matter, including fruits of raspberry (*Rubus*), crab apple (*Malus*) hawthorn (*Crataegus*), pear (*Pyrus*), cherry (*Prunus*), mulberry (*Morus*) and elderberry (*Sambucus*), and wide range of seeds, including those of coniferous and deciduous trees (principally cones and beech mast), and wide variety of vascular-plant seeds, e.g. of thistles (*Cirsium*) and honeysuckle (*Lonicera*), also cereal plants and other grasses; also flowers and buds of willow (*Salix*), alder, birch, aspen (*Populus*), maple (*Acer*) and plum (*Prunus*), and sap of aspen, birch and maple; generally infrequent at birdtables unless in immediate vicinity of woodland, but, where present, takes variety of foods, including sunflower and hemp seeds. Commonly stores food items (more frequently in Europe than in Britain), principally seeds but also some invertebrates (e.g. slugs), usually between Aug and late Feb, behind loose bark, in holes in trees, in wood piles, under moss clumps, among leaf litter and in holes in ground; in C Norway single individual stored c. 80,000 seeds during Aug-Dec, and individual consumption estimated at minimum of 43 seeds per hour. Food stores relocated by memory, rather than by random search, and exploits earliest stored food first. Occurs in pairs throughout year, but occasionally solitary; also (mostly) juveniles not yet with territory) in mixed-species foraging flocks or in small single-species groups of up to 20 individuals, but generally less social than other tits. Forages at all levels in trees and lower vegetation, but prefers middle to lower levels of trees and shrubs. Actively searches foliage and slender branches, and hangs from buds and cones; vigorously strips lichen and moss in search of insect prey, and pulls seeds from thistle-heads; occasionally hovers briefly; in non-breeding season frequently forages on ground in fallen leaves and among dead plants, including on snow-covered ground where

er and more round-headed appearance, glossy upper mantle), generally no pale wingpanel (individuals), also has centres of greater coverts, fuller, and bib slightly smaller or neater; from *P. sinciped* cap, browner upperparts, less black on nape, but has sooty-black or brownish crown to nape; wings of flight-feathers and tail warmer brown, less obscured by white tips, and underparts whiter, but relatively little, mainly in size and plumage. *P. montanus* (less grey) upperparts than nominate, upperparts, and pale buffish-brown neck side, breast and belly more buffish-brown than nominate, but has slightly paler buff upperparts (boundaries), whiter on side of breast and flanks; slightly longer tail, and paler or greyer upperparts, but restricted or absent; *brevirostris* differs from nominate by buff on underparts (but tinged rufous in E of range), forming slight panel on closed wing, pale edges of wing coverts, and paler on underparts, but nominate, but with paler ash-grey or lightly buffish-brown bib; *hensoni* is as last, but slightly browner upperparts (closer to buffish-brown than nominate), buffish below, becoming whiter in worn plumage, and paler, with smaller tail/wing index; *montanus* has a dark brown flight-feathers narrowly edged with buff, and a ragged crest, black or blackish-brown bib on throat, and lower throat, underparts whitish except for a narrow buffish-brown line on throat. Wide variety of call notes, most commonly a 'psittichiu sippichiu', or 'psiu', or slightly different 'see' often repeated several times, or a 'chit' alarm includes sharp 'pit-zit-zit-its', chattering 'ar-tchar' (often preceded by 'pichuu'), and defence of nest or young female gives hissing 'chit' or 'chit' notes. Song, most frequent between mid-evening and dawn, consists of sharp monosyllabic notes, 'schip schip schip' (often preceded by 'chit' or 'chit'), 'chi chi', may be followed by 'swi-swit' (often by *P. montanus*), may continue with longer 'pitchawee-pitchawee' or 'chip-wichu-wichu-wichu' (often by *P. montanus*), or 'chip-wichu-wichu-wichu' (often by *P. montanus*). Male has repertoire of c. 20 song variations, and also give mixture of phrases from different trills, but song and calls vary little throughout the day, only repetition of a single phrase. Subsong is a main song interspersed with whispering and

**Bibliography.** Barnes (1973), Brazil (1991), Brown & Grice (2005), Cheng Tsohsin (1987), Cramp & Perrins (1993), Dementiev *et al.* (1954, 1970), Eck (1980), Etchécopar & Hûe (1983), Flint *et al.* (1984), Gibbons *et al.* (1993), Gill *et al.* (2005), Glutz von Blotzheim & Bauer (1993), Gorman (1996), Haftorn (1997), Hagemeyer & Blair (1997), Handrinos & Akriotis (1997), Harrap & Quinn (1996), Harrison (1982), Hariet (1905, 1923), Hollom *et al.* (1988), Hûe & Etchécopar (1970), Johansen (1944), King *et al.* (1975), Lee Woo-Shin *et al.* (2000), MacKinnon & Philipps (2000), McCarthy (2006), Meyer de Schauensee (1984), Morley (1953), Nilsson, J. *Poecile montanus*

**Other common names:** Songar Tit (*songarus* group)

*P. m. restrictus* (Hellmayr, 1900) — Japan

*P. m. songarus* (Severtsov, 1873) – SE Kazakhstan and Kyrgyzstan (C & E Tien Shan) E to NW China (NW Xinjiang).  
*P. m. affinis* Przevalski, 1876 – NC China (NE Qinghai, Gansu, N Sichuan, Ningxia and SW Shaanxi).  
*P. m. weigoldicus* (O. Kleinschmidt, 1921) – SC China (E Xizang, SE Qinghai, W Sichuan and NW Yunnan).  
*P. m. stoetzneri* (O. Kleinschmidt, 1921) – NE China (SE Nei-Mongol and Shanxi E to Hebei and Henan).

**Descriptive notes.** 11–12 cm; 8–15 g. Medium-sized, broad-headed tit with pale panel on closed wing. Nominative race has forehead to side of crown (down to lower edge of eye), nape and uppermost mantle dull blackish; rest of upperparts, including lesser and median upperwing-coverts, pale grey-brown, greater coverts similar but with darker brown centres; alula and flight-feathers dark greyish, primaries finely fringed pale, secondaries broadly fringed pale or whitish-buff (forming prominent panel on closed wing), tertiaries as secondaries but centres darker or browner; tail greyish-black, outer webs with broad pale buff

fringes; lores, cheek and ear-coverts white, creamy buff on sides of nape; chin and throat dull black, forming ill-defined bib (with whitish tips on side of throat and along lower border); underparts off-white or dull whitish-grey, in fresh plumage with pinkish-buff on breast side and flanks; in worn plumage, upperparts paler or greyer, wingpanel occasionally less prominent, bib slightly larger, and underparts whiter except for warm buffish flanks and undertail-coverts; iris brown to dark brown; bill dark blue-black or blackish, paler edges of both mandibles; legs dark greyish-blue. Differs from *P. palustris* in larger-headed appearance, slightly more extensive dull (not glossy) cap reaching to upper mantle, pale wingpanel, also darker or blackish (not dark brown) centres of greater coverts, remiges and rectrices, slightly larger bib, and more extensively deeper buff on underparts. Sexes alike. Juvenile is similar to adult, but crown duller brown-black, upperparts colder grey-brown, cheeks and ear-coverts pale creamy white or tinged buff, bib slightly paler brown and with white flecks at sides, whiter underparts with buff wash on flanks and undertail-coverts; bill browner than adult, with yellowish cutting edges. Races differ mainly in size, tail length and colour of upperparts and underparts: *kleinschmidtii* is smallest and darkest race, with browner upperparts, creamy-buff cheek to neck side, extensive buff-brown on underparts, flanks olive-brown, bib appears fairly large; *rhenanus* is similar to previous, but upperparts paler, more drab brown, centre of breast and belly white with pale greyish-buff wash, breast side, flanks and undertail-coverts tinged cinnamon-buff; *salicarius* is very similar to last, but with slightly duller brown upperparts, creamy-white cheek to neck side, and underparts with buff or greyish-buff wash only on flanks; *borealis* has blackest crown and nape (may be slightly glossy) of all races, grey upperparts, white cheek to neck side, whitish or pale buff edges of greater coverts (as edges of secondaries and tertiaries), slightly smaller black bib, white or creamy-white breast centre to vent, with pinkish-buff on flanks and undertail-coverts; *uralensis* is similar to previous, poorly defined, has paler or greyer upperparts, white edges of secondaries and tertiaries, mostly whitish underparts, pale pinkish-grey tinge on flanks; *baicalensis* is very similar to last, but has buffish wash on underparts, slightly longer tail; *kamtschatkensis* has very pale greyish-white upperparts, broad white edges of greater coverts, secondaries and tertiaries, outer rectrices broadly edged white, blackish bib slightly larger, underparts mostly white or faintly washed creamy; *anadyrensis* is poorly differentiated, intermediate between previous two; *restrictus* is darker than *kamtschatkensis*, with crown duller and browner, mantle and back grey-brown with sandy tinge, underparts with slightly heavier buffish wash; *sachalinensis* is similar to last but paler or greyer, more noticeably on underparts; *songarus* is slightly larger, with longer bill, slightly rounded tail (outermost feather up to 6 mm shorter than others), dark chocolate-brown crown, warmer, more ochre-brown upperparts, wingpanel indistinct, rear ear-coverts and side of neck washed buffish-brown, some brownish on bib, pinkish-cinnamon wash on flanks; *stoetzneri* is similar to previous, but smaller, somewhat longer-tailed, crown to nape browner, bib darker, upperparts slightly paler, and cinnamon wash on flanks less pinkish; *affinis* is slightly darker than previous, wingpanel indistinct; *weigoldicus* is similar to last, but crown more blackish-brown, upperparts slightly darker, flanks tinged browner. **VOICE.** Generally less vocal than *P. palustris*, and with fairly restricted vocal repertoire. Contact call 2–4 short high-pitched “zi-zi” or “tsi-tsi” notes followed by longer series of more nasal “tchaa tchaa tchaa” or “tchay tchay tchay”, and harsh or scolding notes which may also be given as rolling “tchurrurr”; same notes but at higher pitch, louder and with faster delivery given in alarm; high-pitched “pi” followed by lower “pa” during aggressive encounters; also shorter high “zi”, “sit” or “zit” contact notes when foraging in family group, occasionally extended into “zisi” or “zissit” and thin, drawn-out and downslurred “dzee”, “zieh” or “ziet”; other alarm notes include harsh “pett” or “kett” several times in succession, and “chik-ik-ik-ik” like that of a sparrow (*Passer*), and during courtship a soft descending “didededa” by female and rapid “zi-zi-zi-zi” by male; call of race *songarus* slightly harsher, variable, “psit-zer” or “psit dzee dzee” repeated, also nasal “chiur” and sharp “chit”; *affinis* also gives a series of “sip-sip-sip...” calls, also a more slurred “tsiur-dzee-dzee” and a short, chattering series of “chip-ip-ip-ip” notes; calls of *stoetzneri* similar those of *affinis* but variable, with dissyllabic “ps-zur ps-zur” or longer “tsi-stip-dzah” or “tchip-dzee-dzee” and “dzeeh-dzeeh-dzee”. Song, mostly in early to middle morning throughout year (most frequent in late winter and early spring, and again in late summer), varies considerably between lowland and montane populations, throughout lowland Europe mostly 3–5 downwardly inflected and drawn-out piping “piu piu piu” or “duu duu duu” notes, reminiscent of introductory notes of Wood Warbler (*Phylloscopus sibilatrix*) song; in C Europe (Alps E to N Croatia, also Tatra Mts of Poland–Slovakia), song of alpine populations (mostly nominate race) up to 7 or occasionally 10 soft and monosyllabic or evenly pitched notes as “duh duh duh duh” or with softer “ü ü ü ü”, occasionally as higher-pitched “pe-pe pe-pe pe-pe pee pee”, given in late winter and spring only, and individuals in hilly and submontane areas may give modified or intermediate-type song with slight decline in pitch; in overlap areas at 1000–1550 m, both song types can occur together. In Fennoscandia and E Europe to E Asia song mostly of modified type, with phrases of lowland and montane songs either constant or slightly falling in pitch, in Japan appears to be of two types, in N similar to that of montane areas of C Europe, but in S two or three ringing whistles repeated several times, e.g. “pee-si pee-si pee-si pee-si pee”. Also has weak series of musical, warbling and chattering notes as subsong; also an infrequently heard (apparently mostly in Britain) series of rich warbling notes, similar to several notes of Common Nightingale (*Luscinia megarhynchos*), mixed with softer notes, given in short snatches and not far-carrying. Singing by female infrequent.

**Habitat.** Lowland, submontane and montane forests and woodlands, principally coniferous forests of pine (*Pinus*), larch (*Larix*) and spruce (*Picea*), and in Siberian taiga most frequently in steppe-forest of Siberian stone pine (*Pinus sibirica*), and often in dense and damp areas, especially *Sphagnum* bogs and areas of willows (*Salix*) or alders (*Alnus*) and on tundra edge. In Europe also occurs

in willows, alders and more shrubby vegetation, including elder (*Sambucus*) patches, edges of woods, copses, and hedges, especially along rivers and beside lakes. In Tien Shan occurs in montane conifer forest, also mixed broadleaf woodland with well-developed undergrowth and willow thickets, and lowland to submontane birch (*Betula*) forest; also in riverine and swamp thickets, and occasionally in osier (*Salix*) beds. Occurs from sea-level to tree-line, in Europe up to c. 2000 m, in Altai Mts up to 2300 m, between 800 m and 2400 m in Japan (C Honshu); in China, at 1830–2745 m in Tien Shan, at 2200–4275 m in Sichuan (but breeding not confirmed above 2400 m), and present in summer at 3350–4000 m in Qinghai and at 3840 m (in Mar) and 3960 m (in Jul) in Xizang.

**Food and Feeding.** Mostly invertebrates and larvae, also vegetable matter. In breeding season includes flies (Diptera), lacewings (Neuroptera), mayflies (Ephemeroptera), caddis flies (Trichoptera), bees and wasps (Hymenoptera), ants (Formicidae), beetles (Coleoptera), bugs (Hemiptera), moths (Lepidoptera), scale insects (Coccoidea), centipedes (Chilopoda), spiders (Araneae), harvestmen (Opiliones), mites (Acari), snails (Gastropoda) and earthworms (Oligochaeta). In non-breeding season also grain, principally wheat (*Triticum*), oats (*Avena*), maize (*Zea*) and barley (*Hordeum*), also seeds of burdock (*Arcium*), cowberry, cranberry and bilberry (*Vaccinium*), bramble and raspberry (*Rubus*), snowberry (*Symphoricarpos*), honeysuckle (*Lonicera*), poppy (*Papaver*), rose (*Rosa*), buckthorn (*Rhamnaceae*), and various other plants e.g. hedge woundwort (*Stachys sylvatica*), also (according to availability and abundance) fruits of oak (*Quercus*), rowan (*Sorbus*), ash (*Fraxinus*), birch, alder (also buds), juniper (*Juniperus*), lime (*Tilia*), maple (*Acer*), spindle (*Euonymus*), beech (*Fagus*) and conifer seeds (extracted from cones), also aspen (*Populus*) and willow catkins, pollen of aspen, and sap of birch, maple and aspen. Diet of adults throughout summer divided almost equally between plant and animal food, but amount of plant food increases to c. 75% in winter; nestling diet similar to that of adults, but initially more larvae, principally caterpillars. Stores food behind loose bark, under branch, in bud capsules or in lichen, rarely in ground in steep bank; in S Norway most food cached in Aug–Oct, and at one study site 94.8% of stored items were eaten during winter months; in NW Russia recorded as storing up to 200 items per day in winter and over 4700 items per day in spring, providing estimated annual total of 460,000 items (sufficient for 2–3 times the energy requirement to survive the winter). Usually in pairs, sometimes solitary; sometimes small groups of up to six (in N populations usually adult pair with unrelated juveniles), which form in late summer and disperse in spring; within groups, social structure complex, with dominance hierarchy of males over females and adults over juveniles, social rank affecting access to food and foraging areas (lower-ranking individuals forced to feed in less optimal sites); group frequently becomes basis for mixed-species flocks with addition of conspecifics, nuthatches (Sittidae), Eurasian Treecreeper (*Certhia familiaris*) and Goldcrest (*Regulus regulus*), but usually only where these coincide within territory. Actively forages in middle to lower levels of trees and shrub layer; investigates branches (including undersides), thin twigs and conifer and larch needles, hangs from vegetation and climbs vertical trunks by fluttering, occasionally hovers or pursues insects in flight; may search in ground cover, e.g. brambles (*Rubus*), bracken (*Pteridium*), thistles (*Cirsium*) or hemp-nettles (*Galeopsis*), but rarely descends to ground. Most food items collected from vegetation, and rarely (much less than *P. palustris*) picks or hammers vegetation to extract concealed prey; occasionally holds berries and seedheads of plants under foot and removes seeds. Infrequently visits birdtables. In studies in S England, individuals made up to 1100 foraging visits daily to trees, and during mid-winter estimated to require an average-sized insect every 2.5 seconds in order to maintain condition.

**Breeding.** Season Apr–Jul; one brood. Monogamous; lifelong pair-bond. Territorial; partners remain together within or close to territory (within larger foraging territory) throughout year. Display includes singing and chasing by male, and bowing and wing-shivering by both sexes; male courtship-feeds female both at nest and away from it, and this usually accompanied by begging calls by female and rapid trilling by male. Nest built by female, mostly of bark or wood strips, grass, plant fibres, animal hair and feathers (rarely, moss included), placed in hole or crevice up to 3 m (often less than 1 m, exceptionally to 10 m) from ground in rotting tree trunk or old stump; hole excavated by both sexes, or may adapt existing one, e.g. woodpecker (Picidae) hole, or sometimes drey of squirrel (Sciuridae) used; rarely, nestbox used; territory size varies according to habitat, 5–15 ha. Clutch 5–9 eggs; incubation by female, sometimes starting before clutch complete, incubation period 13–15 days; chicks fed by both sexes, nestling period 17–20 days; young dependent on adults for further 12–15 days, dispersing after 20 days. Longevity 8 years 11 months.

**Movements.** Mainly resident; race *songarus* a short-distance altitudinal migrant, and N populations dispersive and occasionally eruptive; in Europe generally keeps within 5 km of natal area and movements beyond 50 km exceptional, but includes ones up to 167 km in UK and 370 km from Germany to N France. N populations (mostly race *borealis*) E from Finland sedentary when food available, but regularly disperse randomly, most moving S from late Jul to early winter; in years of poor cone crop movements much larger, and thousands of individuals (mostly juveniles) move S, in Europe reaching Sweden and S Norway (up to 600 km SW of place of ringing) between late Aug and early Nov; *borealis* irregular visitor to Britain Sept–May; smaller movements in C Europe, when reaches W & NE Hungary. Similar pattern recorded in Siberia, where S populations largely resident and N ones partly migratory; common in wooded steppe from mid-Aug (occasionally late Jul), and birds apparently of race *baicalensis* occur on passage through middle latitudes and notably around Tomsk in Sept–Oct, with return movement through C Siberia in Apr–May (occasionally early Jun). Large-scale movements usually noticeable along river valleys; generally reluctant to cross large areas of water, may gather in several hundreds in trees at strategic places before attempting to cross.

**Status and Conservation.** Not globally threatened. Common in N parts of range, and the commonest tit in Siberia (abundant along R Yenisey) and Mongolia (but population largely dependent on seed crop from Siberian stone pine); locally very common in C China; common in S Japan but uncommon in N (Hokkaido); breeds locally in N Korea, rare non-breeding visitor S Korea; in Europe, locally common in W but becomes less frequent or scarce in S. Estimated European breeding population 5,000,000–6,000,000 pairs, with largest numbers in Scandinavia and Russia. Breeding densities highest in Siberia, where 30–50 birds/km<sup>2</sup> in dark conifer taiga and pine, rising to 119–142 birds along R Chuna, and 20–30 birds in mixed forest and 6–7 birds in lowland floodplain-forest and meadows. Has extended range in N & C Europe, and since mid-1950s has colonized Harz Mts (Germany) and Bohemia and Moravia (Czech Republic); since 1960s has bred in Hungary, first bred N Greece in 1973 and since 1977 has bred N Denmark; on other hand, range in Britain declined by c. 10% since 1970s, possibly as a result of habitat changes through land drainage, changing climate or increased competition from other parids.

**Bibliography.** Barnes (1975), Brazil (1991), Brown & Grice (2005), Cheng Tsohsin (1987), Cramp & Perrins (1993), Dementiev *et al.* (1954, 1970), Eck (1980), Etchécopar & Hùe (1983), Flint *et al.* (1984), Foster & Godfrey (1950), Gibb (1954, 1960), Gibbons *et al.* (1993), Gill *et al.* (2005), Glutz von Blotzheim & Bauer (1993), Gorman (1996), Haftorn (1993a), Haftorn *et al.* (1998), Hagemeijer & Blair (1997), Handrinos & Akriotis (1997), Harrap & Quinn (1996), Harrison (1982), Hartert (1905, 1921, 1923), Johansen (1944), Jouard (1936), Kvist *et al.* (2001), Lee Wood-Shin *et al.* (2000), MacKinnon & Philipps (2000), McCarthy (2006), Meyer de Schauensee (1984), Perrins (1979), Pravosudov & Pravosudova (1996), Quaisser & Eck (2002), Rasmussen & Anderton (2005), Rogacheva (1992), Svensson *et al.* (1999), Thönné (1962, 1972), Tomek (2002), Vaurie (1957b, 1959), Wernham *et al.* (2002).

## 4. Carolina Chickadee

*Poecile carolinensis*

French: Mésange de Caroline German: Carolinameise Spanish: Carbonero de Carolina

**Taxonomy.** *Parus carolinensis* Audubon, 1834, Charleston, South Carolina, USA.

Until recently present genus normally subsumed into a broad *Parus*, and many authors still prefer that treatment. Genus normally treated as feminine, but no evidence in original description or elsewhere justifies this, so genus is masculine by default. May form a superspecies with *P. montanus* and *P. atricapillus*, possibly also including *P. gambeli* and/or *P. sclateri*. Hybridizes with *P. atricapillus* in narrow band in EC United States (extending from S Kansas E to Pennsylvania, New Jersey and W North Carolina). Geographical variation clinal, with decrease in size and reduction in extent of pale edges of flight-feathers from N to S, also paler from E to W; races thus intergrade widely in overlap areas. Evidence from mitochondrial DNA indicates that E & W populations (which meet approximately along Mississippi–Alabama state lines) have been separated from each other by c. 1 million years; level of divergence does not influence plumage or vocal characteristics, but W populations may meet species status. Four subspecies recognized.

**Subspecies and Distribution.***P. c. atricapilloides* (Lunk, 1952) – SC USA (S Kansas, Oklahoma and N & C Texas).*P. c. agilis* (Sennett, 1888) – SE Oklahoma, SC & E Texas, SW Arkansas and W Louisiana.*P. c. extimus* (Todd & Sutton, 1936) – S Missouri E to Ohio, S Pennsylvania and New Jersey, S to NW Tennessee, NW North Carolina and E Virginia.*P. c. carolinensis* (Audubon, 1834) – N & E Arkansas, S Kentucky and Tennessee E to SE Virginia, S to E Louisiana, S Mississippi and N & C Florida.

**Descriptive notes.** 11.5–13 cm; 9–12 g. Medium-sized, black-capped chickadee with grey-brown upperparts. Nominative race has forehead to crown (including eye area) and nape black; upperparts, including upperwing-coverts, grey or greyish-brown, washed buffish on upper mantle, rump and uppertail-coverts; greater coverts with dark grey centres and pale grey fringes (inner greater fringed paler or buffish-grey), alula and primary coverts blackish, finely fringed pale grey, flight-feathers dark brown, finely fringed greyish-white, longest tertial fringed pale grey or greyish-white; tail dark grey, feathers narrowly edged pale grey, outermost rectrix with white tip; cheek to nape side white, chin and throat sooty black and forming large dark bib (with sharply defined lower edge); centre of breast and belly white or washed buffish, side of breast, flanks and undertail-coverts pale buffish; in worn plumage slightly paler above and below, whitish edges of flight-feathers duller and narrower, and flanks greyish-buff; iris dark brown; bill black or dark bluish-black; legs dull slate-grey. Differs from *P. atricapillus* in slightly smaller size and shorter tail, smaller-headed appearance, somewhat paler upperparts lacking broad white edges on uniformly grey greater coverts, sharply defined lower edge of black bib, buffish (not olive) on breast side, cinnamon-buff on flanks. Sexes alike. Juvenile is very similar to adult, but crown and bib duller or browner, and underparts more uniformly dull buffish. Races differ mainly in size and in depth of plumage coloration: *extimus* is slightly larger than nominate but otherwise poorly differentiated, has slight olive tinge in upperparts, edges of greater coverts buffish-grey, broad edges of flight-feathers slightly paler or whiter, and flanks slightly deeper buff; *atricapilloides* is similar to previous, but upperparts paler/greyer, greater-covert edges whitish-grey, and underparts whiter or creamier buff (whitest in worn plumage), with less buff on flanks; *agilis* is similar to last but slightly smaller, greater-covert edges buffish-grey, narrower pale fringes of flight-feathers (may be tinged buffish on secondaries), and less buff on flanks (may be tinged greyish). Voice. Most frequent call a high-pitched “chic-a-dee”, similar to that of *P. atricapillus* but usually with faster delivery and often run into “chick-a-dee-dee-dee”; also repeats “dee” note in sharp series of scolds, occasionally preceded by or interspersed with harsh “chrrrrrrrrrr”; contact call a thin “tsit” or “psit”, often in series or when flock-members agitated; also, a thin “seet” and a soft twittering “sisisisisisi”; a series of soft and seemingly random notes, often used in aggression, “spee-dee-dee-dee-dee”. Song, throughout year (most frequently in winter and spring), begins with high-pitched “fee” note and continues as a 4-note “see-bee-see-bay”, with first and third notes higher than other two; also variations, e.g. “see-bee-bee” and “tsee-bee-tseebay”.

**Habitat.** Open broadleaf woods, mostly along rivers, streams and canals, also swamp-forest and secondary forest, scrub, and large wooded suburban gardens and parks; in S of range occurs in cypress swamps and edges of pine (*Pinus*) woodlands. Generally in lowlands, but to 850 m in C Texas and to 1400 m in Pennsylvania, 1525 m in Virginia and generally below 1380 m in North Carolina, but to 1850 m where *P. atricapillus* absent.

**Food and Feeding.** Food mostly small invertebrates and their larvae and eggs, including moths (Lepidoptera), bugs (Hemiptera), bees, wasps and ants (Hymenoptera), aphids and leafhoppers (Homoptera), spiders (Araneae); also seeds, especially of poison ivy (*Rhus radicans*), blackberry (*Rubus*), blueberry (*Vaccinium*), honeysuckle (*Lonicera*), mulberry (*Morus*) and Virginia creeper (*Parthenocissus quinquefolia*). Stores food, mostly seeds, nuts and invertebrates, in caches behind loose tree bark, on undersides of branches, in holes in rotting trees or in plant stems. Usually in pairs or small groups, and in non-breeding season may join larger mixed-species foraging flocks; autumn juveniles form loose roaming flocks. Forages in trees and thickets, usually along edges of woodland, acrobatically examining upper and undersides of leaves, twigs and branches and searching among smallest twigs, also bark on trunks of trees; rarely descends to ground. Not infrequently visits feeders.

**Breeding.** Season mid-Feb to early Jun; one brood. Monogamous, with lifelong pair-bond. Territorial, but some nests close together (c. 8 m apart); highest-ranking males and females that survive winter establish territory within non-breeding territory, and lower-ranking individuals forced to depart, although some males may be tolerated as floaters. Courtship includes wing-shivering by both partners, begging calls by female, and feeding of female by male. Nest built by female, mostly of moss, bark strips, grass, plant fibres, animal hair and feathers, extra material added after laying (forming large loose flap, which covers eggs when she is away from nest), placed up to 12 m (usually below 5 m) above ground in hole in rotting tree or stump, hole excavated by pair or old hole of woodpecker (Picidae) adapted; natural crevice or pipe entrance also used, as occasionally is nest of other hole-nesters e.g. Cliff Swallow (*Petrochelidon pyrrhonota*), and nestboxes. Clutch 3–6 eggs, occasionally up to 9; incubation by female, fed by male both on and off nest, period 12–15 days; chicks fed by both parents, nestling period 16–19 days; young become independent after further 21 days. Hatching success of breeding pairs 83% in S Illinois, 91% in Tennessee and 92% in Pennsylvania; number of young fledged per nest 3.5 in Tennessee, 3.9 in Illinois and 5.8 in SE Pennsylvania. Breeds in first year. Recorded longevity 10 years 11 months.

**Movements.** Resident. Little movement, but singles recorded C Kansas, and vagrant in S Texas, Nebraska, Michigan and S Canada (SE Ontario).

**Status and Conservation.** Not globally threatened. Common throughout range. Some reduction in numbers recorded in N Florida.

**Bibliography.** Anon. (1983b, 1998a), Bent (1946), Bloomfield *et al.* (2005), Bronson *et al.* (2005), Dixon (1961), Doherty & Grubb (2002), Farrand (1985), Frechberg *et al.* (2003), Gill, Mstrom & Mack (1993), Gill, Slikas & Sheldon (2005), Harrap & Quinn (1996), Kaufman (1990), Lucas *et al.* (1999), Mayer *et al.* (1982), McCarthy (2006), Mstrom *et al.* (2002), Parkes (1986b), Pyle (1997), Sibley (2000), Smith (1972), Yunk (2003).

## 5. Black-capped Chickadee

*Poecile atricapillus*

French: Mésange à tête noire German: Schwarzkopfmäise Spanish: Carbonero Cabecinegro

**Taxonomy.** *Parus atricapillus* Linnaeus, 1766, Quebec City, Canada.

Until recently present genus normally subsumed into a broad *Parus*, and many authors still prefer that treatment. Genus normally treated as feminine, but no evidence in original description or elsewhere justifies this, so genus is masculine by default. May form a superspecies with *P. montanus* and *P. carolinensis*, possibly also with *P. gambeli* and/or *P. sclateri*. Has been considered conspecific with *P. montanus*, but DNA studies indicate that the two are not closely related genetically. Hybridizes with *P. carolinensis* in narrow band in EC USA (extending from S Kansas E to Pennsylvania, New Jersey and W North Carolina). Geographical variation clinal, and races intergrade widely; paler-flanked birds in S Canada (NC Ontario) sometimes separated as race *anamesus*, but better included within nominate. Nine subspecies recognized.

**Subspecies and Distribution.***P. a. turneri* (Ridgway, 1884) – NW USA (WC & S Alaska) and NW Canada (extreme NW British Columbia).*P. a. occidentalis* (S. F. Baird, 1858) – coastal SW Canada and W USA (S to NW California).*P. a. fortuitus* (Dawson & Bowles, 1909) – inland SW Canada and NW USA (S to NW Idaho).*P. a. septentrionalis* (Harris, 1846) – W & C Canada S to C USA.*P. a. bartletti* (Aldrich & Nutt, 1939) – Newfoundland and Miquelon I.*P. a. atricapillus* (Linnaeus, 1766) – E Canada S to C USA.*P. a. nevadensis* (Linsdale, 1938) – SW USA.*P. a. garrinus* (Behle, 1951) – WC USA.*P. a. praticus* (Oberholser, 1937) – E USA (Appalachian Mts).

**Descriptive notes.** 13–14.5 cm; 9.2–14 g. Medium-sized to large, black-capped and grey-backed chickadee. Nominative race has forehead to crown (including eye area) and nape sooty black; upperparts olive-grey, variably tinged buffish on upper mantle, rump and uppertail-coverts; median and greater upperwing-coverts with dark grey centres, inner two broadly fringed whitish or pale grey, alula and primary coverts blackish, finely fringed pale grey, flight-feathers blackish-brown, finely fringed pale greyish, secondaries with broad white fringes (forming, with greater coverts, a prominent panel), and longest tertial with whitish

fringe and pale grey tip; tail blackish-grey, narrowly edged off-white, outermost two feathers (which slightly shorter than rest) broadly edged white; cheek to side of nape white, chin and throat sooty black and forming large dark bib, sides and lower edge of which broadly tipped whitish (giving irregular edge); white below, breast sometimes washed light buffish, breast side olive-buffish, becoming pinkish-buff (pinkish-grey in spring) on flanks and undertail-coverts, locally (S Canada) with paler flanks (“*anamesus*”); in worn plumage, slightly greyer or duller above and greyish-white below, with whitish edges of wing feathers duller and abraded; iris dark brown or black; bill black or dark brownish-black; legs dull bluish-grey. Differs from *P. carolinensis* in slightly larger size and longer tail, larger-headed appearance, somewhat darker upperparts, broad white edges of greater coverts, broad white edges of inner secondaries and tertials, irregular lower edge of black bib, olive on breast side, cinnamon-buff on flanks and undertail-coverts. Sexes alike. Juvenile is as adult, but crown and bib slightly browner, bib more extensively tipped pale grey at sides, upperparts slightly duller or more brownish, pale base of lower mandible. Races differ mainly in size (particularly wing length), colour of upperparts, extent of pale edges on secondaries, and flank colour: *turneri* is similar to nominate but slightly larger, and upperparts paler buffish-grey, edges of flight-feathers whiter and more extensive, underparts whiter, with sides washed pale buff; *occidentalis* is slightly darker above, with narrower and less distinct whitish edges on remiges and rectrices, duller below, with sides of breast and flanks rich buff (pinkish in fresh plumage); *septentrionalis* has longer wing and tail than nominate, upperparts slightly paler grey with buff wash, flight-feather edges whiter, underparts whiter, with less buff wash on belly and flanks; *fortuitus* is similar to both nominate and previous, with upperparts medium olive-grey, tinged buffish, edges of flight-feathers and tail feathers broader, flanks buffish-tan; *garrinus* is close to last two but paler above, except for brown wash on back, buffish rump, and has broader white edges on flight-feathers and rectrices; *nevadensis* is also similar, but paler grey and less buff on upperparts, with broad edges of remiges and rectrices (all tail feathers fringed white on outer web), and paler below, flanks pale buffish-brown when plumage fresh; *bartletti* resembles nominate, but upperparts darker, edges of wing and tail feathers narrow, duller and washed greyish, and flanks to vent washed buffish-brown (fresh plumage); *praticus* has shorter tail than nominate, and upperparts slightly darker, less buffish, with narrower pale edges of wing and tail feathers, also underparts paler and with more contrast apparent between white centre of breast and belly and dull buff flanks (pinkish when fresh). Voice. Most frequent call “chick-a-dee-dee-dee”, similar to that of *P. carolinensis* but lower-pitched and with slower delivery; also gives “dee” note repeatedly in sharp series of scolding notes; contact call a thin “tsit”, “psit” or “tsleet”, often in series, or when agitated becoming rattling “tsleet-slit-slit-slit-slit”; also, softer “fee-bee” and more individual thin “seet” and a soft twittering “sisisisisisi”; begging call by female to male in breeding season a descending “zee-zee-zizizi-ziu”. Song, throughout year (mostly from early Dec to mid-summer), a clear whistled “fee-bee” or “fee-bee-bee”; responds rapidly to whistled imitations of song.

**Habitat.** Open deciduous and mixed forests and woods. Favours birch (*Betula*) and alder (*Alnus*) and spruce–fir (*Picea–Abies*) and pinyon–juniper (*Pinus–Juniperus*) forests, also willows (*Salix*) and cottonwoods (*Populus*) along river valleys, wooded agricultural areas, orchards, parks and suburban gardens; in non-breeding season found in wider variety of bushed and scrubby habitats. Mostly in lowlands, to 915 m in NW California, to 1220 m in New York and to 1920 m in Idaho; in Appalachians largely at higher elevation than *P. carolinensis* except on some of the higher summits

(e.g. Great Smoky Mts); in SE of range largely montane, breeding above 1200 m in North Carolina and Tennessee, and in Rocky Mts breeds at up to 2775 m in Colorado and at 2285–3200 m in New Mexico.

**Food and Feeding.** Food mostly small insects and larvae (principally caterpillars), also spiders (Araneae), small snails and slugs (Gastropoda), centipedes (Chilopoda). Also vegetable matter, including seeds, mostly of hemlock (*Tsuga*), also berries including blackberries (*Rubus*), blueberries (*Vaccinium*), honeysuckle (*Lonicera*), bayberry and mayberry (*Myrica*) and poison ivy (*Rhus radicans*); sap of sugar maple (*Acer saccharum*) also taken. Frequently visits birdtables, where takes variety of food items including animal fat and dead fish; most such items carried to secluded perch for swallowing. Stores food, mostly seeds and dead spiders, in caches in variety of locations, including crevices in tree trunks, behind loose bark, in bundles of dead leaves and pine needles, and in earth or snow; retrieves items from stores up to a month later. Often tame or confiding. Usually alone, in pairs, or in small groups of about twelve individuals (but up to 18 in areas where food easily available from birdtables); in autumn groups of juveniles gather for short periods; flocks have well-established social hierarchy, but low-ranking members of group may forage alone or join other flocks of same species, though usually returning to roost with original group. Also, winter groups often form basis for larger groups of mixed-species flocks. Actively forages at middle to low levels of trees and bushes, examining tree bark; hangs from branches and slender twigs, and gleans among foliage (apparently able to read clues to invertebrate presence, e.g. leaf damage by caterpillars); also occasionally hovers. In winter forages also in low branches and vegetation and on ground, including in areas some way N of breeding range. Occasionally pursues insects in flight.

**Breeding.** Season late Mar to early Jul; generally one brood. Monogamous, lifelong pair-bond; pair formation takes place throughout year, but predominantly in autumn and late winter to early spring. Courtship includes wing-shivering displays, calling softly, and feeding of female by male. Nest built by female, mostly of moss, bark strips, conifer needles, grass, plant fibres, wool, animal hair, gossamer and feathers, placed up to 7 m from ground in crevice or hole in tree, most frequently in hole or cavity in broken branch of decaying tree, occasionally in fence post, nest-hole excavated by both sexes; sometimes old hole of woodpecker (Picidae) utilized, or nestbox used in areas where natural sites scarce. Clutch 6–8 eggs; incubation by female, fed by male, period 11–14 days; chicks fed by both sexes, nestling period 12–16 days; young feed themselves within seven days of fledging, but remain with adults for further 21–28 days. Breeds in first year. Recorded longevity 12 years 5 months.

**Movements.** Largely resident, but descends from higher altitudes short distances to lower levels; also eruptive. In N of range, resident in areas of Alaska and Canada where mid-winter daylight limited to c. 3–5 hours and temperature may drop to –52°C. In years when seed crop poor or fails, large numbers (mostly juveniles) move S between mid-Sept and late Nov, usually to within 5 km of breeding range; movements usually during daytime and flocks often highly visible, especially along river valleys and at strategic points where they are reluctant to cross open water; largest recorded movement involved 36,000 individuals near Rochester, in New York, in Oct 1961. In breeding season has wandered N to Point Barrow (N Alaska), and in non-breeding season occurs irregularly S to Missouri, Oklahoma, Kentucky and Virginia; vagrant in Arizona.

**Status and Conservation.** Not globally threatened. Common to locally uncommon; generally widespread. Uncommon in NW (Alaska) and SW (Nevada and California). Population level fluctuates periodically, with peaks of cycle every 2–3 years. General increasing trend in numbers in E parts of range. Winter survival reliant on cached food supplies, especially in N populations; elsewhere, increased overwinter survival recorded when feeders and birdtables available.

**Bibliography.** Anon. (1983b, 1998a), Armstrong (1991), Baker & Gammon (2007), Bent (1946), Bronson *et al.* (2005), David & Gosselin (2002a), Dixon (1961), Farrand (1985), Ficken (1981), Ficken *et al.* (1978), Giff, Mostrom & Mack (1993), Gill, Slikas & Sheldon (2005), Godfrey (1986), Haftorn *et al.* (1998), Harrap & Quinn (1996), Kaufman (1990), Martin & Norris (2007), McCarthy (2006), Mennill & Otter (2007), van Oort *et al.* (2007), Phillimore & MacDougall-Shackleton (2007), Pyle (1997), Ratcliffe *et al.* (2007), Sibley (2000), Smith *et al.* (1999), Sturman (1968a, 1968b), Yonick (2003).

## 6. Mountain Chickadee

### *Poecile gambeli*

**French:** Mésange de Gambel **German:** Gambelmeise **Spanish:** Carbonero Montañés  
**Other common names:** Gambel's Chickadee

**Taxonomy.** *Parus gambeli* Ridgway, 1886, “about one day’s journey west of Santa Fé, New Mexico”, USA.

Until recently present genus normally subsumed into a broad *Parus*, and many authors still prefer that treatment. Genus normally treated as feminine, but no evidence in original description or elsewhere justifies this, so genus is masculine by default. Has been placed in a superspecies with *P. sclateri*, sometimes including also *P. montanus*, *P. carolinensis* and *P. atricapillus*; has also been considered possibly conspecific with *P. superciliosus* or placed with it in a superspecies; further research required. Geographical variation largely clinal, and races intergrade; additional proposed races are *wasatchensis* (described from Wasatch Mts, in Utah), synonymized with *inoensis*, but sometimes included within nominate, and *grinnelli* (Idaho) and *abbreviatus* (California), both merged with *baileyae*. Birds in Davis Mts, in SW Texas, have been proposed as a further race on basis of small size. Four subspecies recognized.

#### **Subspecies and Distribution.**

- P. g. baileyae* (Grinnell, 1908) – Pacific slope of Rocky Mtns in W Canada and W USA.
- P. g. inoensis* (Grinnell, 1918) – W USA (SE Oregon and S Idaho S to CE California and NW Arizona).
- P. g. gambeli* (Ridgway, 1886) – WC USA (E Rockies from C Montana S to New Mexico and W Texas)
- P. g. atratus* (Grinnell & Swarth, 1926) – extreme NW Mexico (N Baja California).

**Descriptive notes.** 13–15 cm; 8–2–13.5 g. Medium-sized, black-capped chickadee with narrow white supercilium. Nominative race has forehead to crown and nape sooty black, upper lores/side of forehead and narrow supercilium (fading over ear-coverts) white, rest of lores and broad line through eye and across ear-coverts to nape side black; upperparts, including upperwing-coverts, grey-brown or tinged buffish, median coverts (broadly) and greater coverts (narrowly) edged pale grey; primary coverts finely fringed pale grey; flight-feathers grey-brown, finely fringed pale greyish-white on secondaries, whitest on in-

ner primaries and pale grey on longest tertials; tail grey-brown, outermost two feathers narrowly edged of flight-feathers and tail outer and abraded, underparts dusky and less whitish, iris dark reddish-brown to blackish; bill black or dark brownish-black; legs lead-grey, to blackish. Differs from *P. g. baileyae* in:

whiter underparts, from worn-plumage *P. atricapillus* in pale supercilium, longer bill, shorter tail.

Races differ rather little; *inoensis* is as nominate, but bill slightly longer and thinner, supercilium less distinct; *grinnelli* has slightly longer and thinner bill, *baileyae* has supercilium narrower and often shorter, upperparts darker.

Nominate, birds from Canada S to E Washington and Montana (“*grinnelli*”), smaller-billed, slightly darker grey with olive tinge above, and flanks buffish-tinged grey, birds from W Washington S to N California are smaller-billed, darker grey.

Most birds are sedentary, but some are nomadic, and some are migratory. In winter, they move to lower elevations and to more open areas.

“fee-bee”, or run into longer “fee-fee-fee, fee-bee-bee”, or plaintive “wee-chee-chee” or “dee-dee-dee”; occasionally a series of “fee-bee-bay” (similar to “three blind mice”) or “lee-chee-chee-chee”.

**Habitat.** Montane conifer forest and woodlands, including open and dense stands of hemlock (*Tsuga*), together with deciduous woodland, particularly American aspen (*Populus tremuloides*), oaks, willows (*Salix*) and cottonwoods (*Populus*); also more open areas of chaparral with scattered trees. In non-breeding season in similar habitat at lower levels, including shrubby areas of huckleberries (*Celtis*), and conifers in urban and suburban areas. Occurs at 1830–3350 m in Rocky Mts, above 730 m in NW California, at 2090–3660 m in New Mexico, and at 1500–3000 m in NW Mexico (Baja California); in non-breeding season also down to 900 m W of Rocky Mts and to 585 m in NW Mexico, but many still found in montane areas above 1525 m.

**Food and Feeding.** Food mainly small invertebrates, including adult and larval moths (Lepidoptera) and sawflies (Hymenoptera), bugs (Hemiptera), weevils and other beetles (Coleoptera), leafhoppers and scale insects (Homoptera) and spiders (Araneae). In breeding season, also aphids (Aphidoidea) (mostly in autumn); in autumn and winter takes conifer seeds, buds and berries. May visit birdtables for various items. Stores food, mostly seeds, throughout year, for use mainly during winter. Large seeds and prey items held in foot against perch and eaten in portions; hard-shelled seeds are often crushed in bill.

Individuals (usually paired birds), with established feeding hierarchies between males and pairs, may also join mixed-species foraging flocks. Actively forages in middle to lower levels of trees, including searching of trunks, gleaning by foliage of outer branches, hanging from slender branches and among twigs, in particular needle clusters; occasionally descends to ground.

**Breeding.** Season Apr–Jul; normally one brood, but in N California occasionally two. Pairs for

Nest built by both sexes, mostly of moss, grasses, bark strips, plant fibres, animal hair and feathers, in (Picidae) hole, or occasionally in ground in rodent hole under rocks, frequently in clearing in along woodland edge; nestboxes and holes in buildings and drainpipes also utilized; site often reused in subsequent years. Clutch 5–9 eggs, exceptionally 12; incubation by female, fed by male.

Recorded longevity 18 years.

**Movements.** Resident, but with some short-distance altitudinal movement. From early Sept some descend to foothills, valleys and adjacent plains (but many resident above 1525 m), returning from late Feb onwards; occasional late-summer ascent above breeding area to feed along tree-line. An uncommon winter visitor to coast of Washington and California (including S desert areas) and N Baja California, and in E of Oklahoma, Vagrant in Alaska, Saskatchewan, S Dakota and Nebraska.

**Status and Conservation.** Not globally threatened. Common in most of range; fairly common in E areas of range in Canada, but rare in Yukon.

**Bibliography.** Anon. (1983b, 1998a), Armstrong (1991), Baker & Gammon (2007), Bent (1946), Bronson *et al.* (2005), David & Gosselin (2002a), Dixon (1961), Farrand (1985), Ficken (1981), Ficken *et al.* (1978), Giff, Mostrom & Mack (1993), Gill, Slikas & Sheldon (2005), Godfrey (1986), Haftorn *et al.* (1998), Harrap & Quinn (1996), Kaufman (1990), Martin & Norris (2007), McCarthy (2006), Mennill & Otter (2007), van Oort *et al.* (2007), Phillimore & MacDougall-Shackleton (2007), Pyle (1997), Ratcliffe *et al.* (2007), Sibley (2000), Smith *et al.* (1999), Sturman (1968a, 1968b), Yonick (2003).

## 7. Mexican Chickadee

### *Poecile sclateri*

**French:** Mésange grise **German:** Graufänkchen **Spanish:** Carbonero Mexicano  
**Other common names:** Grey-sided Chickadee

**Taxonomy.** *Parus sclateri* (Grinnell, 1908), “about one day’s journey west of Santa Fé, New Mexico”, USA.

Until recently present genus normally subsumed into a broad *Parus*, and many authors still prefer that treatment. Genus normally treated as feminine, but no evidence in original description or elsewhere justifies this, so genus is masculine by default. Has been placed in a superspecies with *P. gambeli*, sometimes including also *P. montanus*, *P. carolinensis* and *P. atricapillus*; has also been considered possibly conspecific with *P. superciliosus* or placed with it in a superspecies; further research required. Geographical variation largely clinal, and races intergrade; additional proposed races are *wasatchensis* (described from Wasatch Mts, in Utah), synonymized with *inoensis*, but sometimes included within nominate, and *grinnelli* (Idaho) and *abbreviatus* (California), both merged with *baileyae*. Birds in Davis Mts, in SW Texas, have been proposed as a further race on basis of small size. Four subspecies recognized.

#### **Subspecies and Distribution.**

- P. s. baileyae* (Grinnell, 1908) – Pacific slope of Rocky Mtns in W Canada and W USA.
- P. s. inoensis* (Grinnell, 1918) – W USA (SE Oregon and S Idaho S to CE California and NW Arizona).
- P. s. gambeli* (Ridgway, 1886) – WC USA (E Rockies from C Montana S to New Mexico and W Texas)
- P. s. atratus* (Grinnell & Swarth, 1926) – extreme NW Mexico (N Baja California).

*P. s. garzai* (A. R. Phillips, 1986) – NE Mexico.  
*P. s. rayi* (A. H. Miller & Storer, 1950) – S Mexico.

**Descriptive notes.** 12.5–13.5 cm; 7.5–11 g. Medium-sized, black-capped chickadee with olive-grey upperparts. N nominate race has forehead to crown (including eye region) and nape black, crown often with glossy blue tips (in fresh plumage); nape feathers often raised to form crest when alarmed or agitated; upperparts olive-grey, paler or more heavily olive on rump and uppertail-coverts, greater upperwing-coverts with fine whitish tips, centres of median and greater coverts darker grey, fringed olive-grey, alula and primary coverts dark grey to blackish, the latter finely fringed olive-grey; flight-feathers blackish-grey, finely fringed

olive-grey on secondaries and on longest tertial, and paler on edges of primaries; tail dark grey, narrowly edged dull olive-grey; lores and cheek to side of nape white; chin and throat to centre of upper breast sooty black, forming large dark bib, sides and lower edge of which broadly tipped whitish (giving irregular lower edge); upper breast dull white or off-white, rest of underparts pale grey or smoke-grey, flanks washed slightly darker; in worn plumage, olive-grey edges of flight feathers duller and abraded, and bib more extensive and sharply defined; iris brown; bill black or greyish-black; legs dull bluish-grey. Sexes alike. Juvenile is as adult, but crown and bib slightly browner (lacking gloss), bib more extensively tipped pale grey at sides. Races differ only little: *eidos* is similar to nominate but slightly larger, upperparts and flanks slightly paler and greyer, lacking olive tinge; *garzai* has upperparts cold grey, and flanks light grey with light tinge of olive; *rayi* is as nominate, but upperparts and flanks more heavily tinged olive, rump tinged dull brown, and breast may be tinged yellowish. Voice. Calls include drawn-out, buzzy and insect-like “szree” or “szree-szree” or “sschleer”, sometimes in longer series of “szree-zee, szree-szreep, zeep” or interspersed with hissing notes as “tzee tzee tzee shhhh shhhh”; also a sharp “szip”, “tip”, “tsip” or “tseet” and thinner or higher-pitched “sip”, singly or repeated; also a harsh or hoarse and nasal “char”, “schaa” or “dzaa”, alarm a high-pitched “see-see-see” or more sibilant “zee-zee...” at approach of predator. Song, in autumn and early to middle spring, a series of short and loud unmusical phrases, “peeta peeta peeta” or “si-cha si-cha...”, frequently repeated.

**Habitat.** Open montane conifer forests and deciduous woodland. In Mexico breeds principally in oak (*Quercus*) with scattered pine (*Pinus*) or junipers (*Juniperus*) or pine-alder (*Pinus-Alnus*), and at higher altitudes in pine and fir (*Abies*) forests, with highest densities in pine-alder and fir forests; in S USA breeds in large open stands of ponderosa pine (*Pinus ponderosa*) and mixed stands of Engelmann spruce (*Picea engelmannii*) and Douglas firs (*Pseudotsuga menziesii*). Post-breeding dispersal also to other habitats, including oak-pine and Arizona cypress (*Cupressus glabra*). Breeds above 2000 m in S USA and between 1900 m and 3510 m in Mexico; in non-breeding season also lower, recorded down to c. 1500 m.

**Food and Feeding.** Details of diet not well known, presumably includes small invertebrates and larvae, also some seeds. Storing of food by captives documented, but caching not recorded in the wild. Usually in pairs or in small flocks of up to 13 individuals; often joins mixed-species foraging flocks totalling up to c. 100 individuals and containing several congeners, together with *Baeolophus wollweberi*, nuthatches (*Sitta*), kinglets (*Regulus*), Brown Creeper (*Certhia americana*), wrens (Troglodytidae) and vireos (Vireonidae). Forages in lower and middle levels of trees (frequently higher in non-breeding season) and shrubs, examining branches, twigs, slender foliage and open pine cones; hangs from leaves and twigs; occasionally hovers and pursues insects in flight. Rapidly hammers oak galls and acorns with blows from bill to open and remove parasitic insect larvae.

**Breeding.** Not well known. Season early Apr to mid-Jun; probably single-brooded. Monogamous. Courtship includes crouching and begging actions with quivering wings by female, accompanied by soft calls, and courtship-feeding of female by male. Nest built by female, material gathered by both sexes; made mostly of moss, plant fibres and animal hair, placed up to 18 m above ground in hole or cavity (possibly excavated by the pair itself) in dead tree or stump (usually pine or oak), or behind loose bark, or nestbox utilized; female recorded as adorning nest entrance with crushed beetles (Coleoptera), possibly using chemicals released by the insects as predator-deterrent. Clutch 5–9 eggs; incubation by female, fed by male; both sexes feed nestlings; no information on duration of incubation and fledging periods.

**Movements.** Resident, but some move altitudinally to lower levels from mid-Aug onwards; has wandered slightly N of breeding range in S USA.

**Status and Conservation.** Not globally threatened. Common to locally abundant in most of Mexican range, but uncommon in S Oaxaca; in USA, common in Arizona and uncommon in New Mexico. Total population in New Mexico estimated to be between 200 and 300 pairs. In Arizona (Chiricahua Mts), breeding densities of 1.7 pairs/10 ha in ponderosa pine, rising to 6.4 pairs in spruce-fir forest. Has declined in parts of C Mexico as a result of logging and increases in livestock grazing.

**Bibliography.** Anon. (1983b, 1998a), Bent (1946), Dixon (1961), Farrand (1985), Ficken (1990), Ficken & Nosedal (1992), Gill *et al.* (2005), Harrap & Quinn (1996), Howell & Webb (1995), Kaufman (1990), Pyle (1997), Sibley (2000), Sigler-Ficken *et al.* (1994).

## 8. White-browed Tit

### *Poecile superciliosus*

**French:** Mésange à sourcils blancs **German:** Weißbraunenmeise **Spanish:** Carbonero Cebijablanco

**Taxonomy.** *Poecile superciliosus* Przevalski, 1876, Gansu, north China.

Until recently present genus normally subsumed into a broad *Parus*, and many authors still prefer that treatment. Genus normally treated as feminine, but no evidence in original description or elsewhere justifies this, so genus is masculine by default. Has been considered conspecific with *P. gambeli* or placed with it in a superspecies; further research required. Monotypic.

**Distribution.** C & S China: E Qinghai E to S Gansu and N Sichuan, and NE & SE Xizang.

**Descriptive notes.** 13.5–14 cm; 10.1–12.4 g. Large, stocky, long-tailed tit with black cap and prominent white supercilium. Male has crown to nape dull black, long white supercilium from forehead (except narrowly in centre) rearwards, tapering on nape side; lores and broad eyestripe to over ear-coverts black; upperparts dark greyish-olive (variable, in SE Qinghai and NW Sichuan more brownish-grey), median and greater upperwing-coverts with dark grey-brown centres and broad greyish-olive fringes; flight-feathers blackish-brown, fringed pale greyish, secondaries with fine white tips, tertials fringed olive-grey; tail dark grey-brown, feathers narrowly edged paler grey and tipped whitish, outer web of outermost feather dull whitish; cheek to side of nape dull greyish-tinged cinnamon, moustachial region paler cinnamon; chin and throat sooty black, forming large dark bib, underparts pale pinkish to pinkish-cinnamon (in SE Qinghai and NW Sichuan often

see” usually in series, also thin “stip” or “tip” and dry, insect-like rattling “trrrrrr” or “tsirrrr” given in isolation or with other calls; alarm a series of “si”, “sip” or “tchip” notes with varying emphasis or run together in cadence, “tsi-sit-sit-sit-sit-sit-sip”, similar to calls of nuthatches (Sittidae). Song complex and fairly variable, usually includes variety of call notes or protracted notes, comprising a whistled “tsee-tsee-tsee”, ringing “pee” or “pwi-pee”, whistled “peta-peta-peta...”, loud clicking “tchip tchip” and prolonged rattling “tsirrrrr” in combinations, e.g. “tsee-tsee-tsee-pwi-pee, tchip-tchip-pwi-pee, tsirrrrr-pwi-pee, tsee-tsee-tsee-tsee tir ir ir ir ir ir ir ir ir ir...”, “peta-peta-peta”.

**Habitat.** Breeds in dwarf alpine rhododendron (*Rhododendron*), scrub and bushes, including willow (*Salix*), barberry (*Berberis*), buckthorn (*Rhamnus*) and honeysuckle (*Lonicera*), usually along watercourses between 3200 m and 4235 m. In non-breeding season frequents taller vegetation, including rhododendron and open edges of spruce (*Picea*) forest, and recorded also at lower altitudes in poplar (*Populus*) groves.

**Food and Feeding.** Diet little known, but includes small invertebrates and larvae, also some seeds. Occurs in pairs during breeding season, occasionally with additional individual present; in non-breeding season in small groups or parties of up to twelve individuals, when often in company with White-browed Tit-warbler (*Leptopoeile sophiae*). Forages low down in vegetation; fairly shy but typically active, and climbs to tops of taller plants before moving on to the next.

**Breeding.** Poorly known. Season at least May and Jun. Nest consists almost entirely of grass, placed in hole among roots of plants and rocks or in disused rodent burrow. No data on clutch size; eggs incubated by female, fed on and near nest by male. No other information.

**Movements.** Not well known. Considered to undertake short-distance altitudinal shifts; possibly longer movements in times of particularly severe weather, when recorded at lower levels in spruce forests and poplar groves.

**Status and Conservation.** Not globally threatened. Uncommon or locally common.

**Bibliography.** Cheng Tsohsin (1987), Eck (1980), Etchécopar & Hile (1983), Gill *et al.* (2005), Harrap & Quinn (1996), Hartert (1905), MacKinnon & Philipps (2000), Martens & Gebauer (1993), Meyer de Schauensee (1984), Rasmussen & Anderton (2005), Schäfer & Meyer de Schauensee (1938), Vaurie (1959).

## 9. Rusty-breasted Tit

### *Poecile davidi*

**French:** Mésange de David **German:** Davidmeise **Spanish:** Carbonero de David  
**Other common names:** Red-bellied/Pere David’s Tit

**Taxonomy.** *Poecile Davidi* Berezowski and Bianchi, 1891, southern Gansu, China.

Until recently present genus normally subsumed into a broad *Parus*, and many authors still prefer that treatment. Genus normally treated as feminine, but no evidence in original description or elsewhere justifies this, so genus is masculine by default. Has been considered conspecific with *P. lugubris*, but possibly more closely allied to *P. superciliosus*; further research required. Monotypic.

**Distribution.** C China: S Gansu S to S Sichuan, also S Shaanxi and W Hubei.

**Descriptive notes.** 12–13 cm; 10–12.5 g. Medium-sized, black-capped tit with fluffy white cheeks and cinnamon underparts. Has forehead to crown (down to bottom of eye) and nape black (often slightly glossy), side of neck rufous (forming half-collar); upperparts brown to brownish-olive, median and greater upperwing-coverts dark brown, broadly fringed brownish-olive, alula and primary coverts dark brown, finely fringed pale buff, flight-feathers brown, finely fringed pale buffish-brown (slightly paler on edges of outer primaries); tail brown to brownish-olive; cheek to nape side white, feathers loose or fluffy; chin and throat

sooty black, forming large dark bib, sides and lower edge of which rather indistinct; underparts cinnamon, slightly paler on centre of belly; in worn plumage, slightly paler brown on upperparts, and pale edges of flight-feathers usually abraded; iris dark brown or black; bill black or dark brownish-black; legs dull lead-grey to black. Sexes alike. Juvenile is as adult, but cheeks and ear-coverts washed yellowish or yellowish-buff, underparts paler or tinged yellowish, tail feathers have pointed tips. Voice. Calls include “sip” or “tsip”, “tis”, “psit” and harder “chit”, “sit” or “ssi”, also more drawn-out “chi-it-it” and a “tsip-tzee”; also “chic-a-dee”-type call given as song, “tsip-zee, tsip zee” or “tsip zee zee”.

**Habitat.** Mature mixed forest, usually including spruce (*Picea*), fir (*Abies*), pine (*Pinus*), birch (*Betula*), poplar (*Populus*), willow (*Salix*), alder (*Alnus*) and oak (*Quercus*), with shrub layer of bamboo, frequently in areas of red-barked birches. Occurs between 2135 m and 3400 m; similar habitat at slightly lower level in non-breeding season, e.g. recorded between 2200 m and 3050 m throughout winter in Sichuan.

**Food and Feeding.** Food not well known; presumably includes small invertebrates, larvae and seeds. Usually in pairs in breeding season, and in small groups of up to ten individuals in late summer and in non-breeding season. Agile, actively forages in upper and canopy levels of trees, also outer edges of middle levels and occasionally in shrubs; examines outer foliage and buds.

**Breeding.** Poorly known. Season at least May. Nest includes lichens and possibly moss, placed 4–10 m from ground in hole or cavity in decaying or rotting tree trunk or stump. Incubating female fed by male. No other information.

**Movements.** Resident; some short-distance movements to slightly lower levels in non-breeding season.

**Status and Conservation.** Not globally threatened. Restricted-range species: present in Central Sichuan Mountains EBA. Rare to locally not uncommon. Rather poorly known species. Relatively

small range and rapid rate of forest clearance within it give cause for concern over the long-term future of this parid.

**Bibliography.** Cheng Tsohsin (1987), Échécoar & Hûe (1983), Gill *et al.* (2005), Harrap & Quinn (1996), Hartert (1905), MacKinnon & Philipps (2000), Meyer de Schauensee (1984), Stepanyan & Loskot (1998), Vaurie (1959).

## 10. Siberian Tit

### *Poecile cinctus*

**French:** Mésange lapone **German:** Lapplandmeise **Spanish:** Carbonero Lapón  
**Other common names:** Alaskan Tit, Taiga/Grey/Grey-headed Chickadee (*lathamii*)

**Taxonomy.** *Parus cinctus* Boddaert, 1783, Siberia.

Until recently present genus normally subsumed into a broad *Parus*, and many authors still prefer that treatment. Genus normally treated as feminine, but no evidence in original description or elsewhere justifies this, so genus is masculine by default. Forms a superspecies with *P. hudsonicus* and *P. rufescens*, and all have sometimes been treated as conspecific. Regularly hybridizes with *P. montanus*. Races intergrade, and boundaries between them poorly defined; ranges listed are provisional. Four subspecies recognized.

#### **Subspecies and Distribution.**

*P. c. lapponicus* (Lundahl, 1848) – Fennoscandia (except S) and N European Russia.  
*P. c. cinctus* (Boddaert, 1783) – NE European Russia and Siberia E to Bering Sea and Kamchatka, S to L Baikal and NC Mongolia.  
*P. c. sayanus* Sushkin, 1904 – S Siberia (Altai E to S Baikal area) and NW Mongolia.  
*P. c. lathamii* (Stephens, 1817) – NW USA (W & N Alaska) and NW Canada.

**Descriptive notes.** 13.5–14 cm; 11–14.3 g. Medium-sized, large-headed tit with loose fluffy plumage, grey to brown crown and brown upperparts, and black bib. Nominative race has forehead to crown and nape dark brownish or greyish-brown, lores and side of crown to over ear-coverts darker, blackish-brown; mantle, back and scapulars pale tan to light warm brown with very slight cinnamon tinge, uppertail-coverts the same or slightly buffish-brown; plumage somewhat variable, palest and greyest in N Russia (Taymyr Peninsula), brownest in NE Siberia and SE of L Baikal; lesser upwinging-coverts as scapulars,

median coverts broadly fringed brownish-grey, greater coverts with darker centres and fringed white; alula and primary coverts blackish, flight-feathers blackish-grey with pale or whitish-grey fringes (forming pale panel on closed wing), tertiaries as secondaries but slightly more broadly edged pale greyish; tail greyish-black, with broad pale buff edges of outer feathers; cheek and ear-coverts white, rear neck side off-white; chin and throat sooty brown, forming dark bib, with fine whitish tips on sides of throat and along lower border; underparts white or lightly washed buff, flanks brownish-buff, undertail-coverts pinkish-buff; in worn plumage, upperparts slightly paler or greyer, pale fringes of flight-feathers slightly whiter or abraded, bib slightly larger and better defined, and underparts whiter except for buffish flanks and undertail-coverts; iris dark brown; bill dark brown to black; legs bluish-grey to dark greyish-blue. Differs from *P. hudsonicus* in slightly larger size, greyer crown to back, whiter neck side, broader whitish edges on tertiaries and inner secondaries, and paler brownish-buff flanks. Sexes alike. Juvenile is similar to adult, but crown duller brown-black, upperparts duller grey-brown, cheeks and ear-coverts pale creamy white or tinged buff, bib larger and slightly paler brown and with white tips at sides, underparts whiter, buff wash on flanks and vent. Races differ little: *lapponicus* has tawny-brown upperparts with heavier cinnamon-brown tone, and fringes of greater coverts, secondaries and tertiaries narrower and less white; *sayanus* is very similar to nominate, but wing and bill slightly larger, crown greyer, and upperparts and flanks tinged more heavily rufous; *lathamii* is also similar to nominate, but upperparts and underparts on average slightly greyer, and flanks more extensively buff-brown (or tinged pinkish in fresh plumage). **Voice.** Contact calls include thin "tsit" or disyllabic "chit-sit", as well as nasal "tchay" or "dschee" and hoarse "psiup" (often as 3-note "psiup-psiup-psiup"); more frequently a "zi-zi tah tah", confusingly similar to that of *P. montanus*, and often given as part of longer series, "tsi-tsi ziew, tsi-tsi-zieuuw-ziew" or "sisiit-sisiit-see dza-dza-dza-dza-dza"; occasionally a harsher "char-char-char", also harsh "schaar" and high-pitched "ziew"; soft "see" note during display, and female on nest gives hissing anti-predator display similar to that of other tits. Song comprises short shrill notes, "shrii-shrii...", "tschi-tschi...", often included in mellow series of "chi-chi-chi-chi-diddle-wi" or more variable "prrrrrr-prrrrrrree" or rising "ptri-poi"; compared with other tits, song not loud or far-carrying.

**Habitat.** Lowland conifer forests, mostly of old-growth spruce (*Picea*) but also larch (*Larix*) and pine (*Pinus*, particularly *P. sibirica*), especially in areas with dead or decaying trees; in S & E Siberia also in submontane and montane birch (*Betula*) forests, riverine forest and adjacent birches and willow (*Salix*) thickets running through conifer forests; N of tree-line and tundra edge also occurs in dwarf and mature willows along rivers and creeks, and in montane areas on alpine heath. In non-breeding season, found in similar habitat as well as in alders (*Alnus*) and aspens (*Populus tremula*). Also found in dwarf scrub including Labrador tea (*Ledum palustre*).

**Food and Feeding.** Food small invertebrates, principally bugs (Hemiptera) including aphids (Aphidoidea), moths (Lepidoptera), flies (Diptera), caddis flies (Trichoptera), beetles (Coleoptera), spiders (Araneae) and snails (Gastropoda); also seeds, particularly of spruce, pine, juniper (*Juniperus*), larch, birch and rose (*Rosa*). Visits birdtables and refuse tips for scraps; recorded also as eating fat from frozen caribou (*Rangifer*) carcasses. Stores food throughout year in variety of caches, e.g. crevices behind loose bark, in lichen clusters and clumps of needles, and estimated that an individual stores up to 500,000 items (majority pine seeds) per year and exploits these during winter, when essential for survival (but in most years only 15% of stored food utilized); in experiments, food store apparently relocated by accident, instead of by memory; juveniles cache only c. 20% of the volume stored by adults in autumn, and this generally insufficient for winter survival (hence juveniles have greater dependence on winter movement and higher mortality rate). Usually in pairs or small parties, occasionally in mixed-species flocks or (especially juveniles) with parties of *P. montanus*; dominant over *P. montanus* in winter flocks and over *Parus major* at feeding sites. Actively and methodically forages in trees, searching branches, leaves and conifer needles; hangs from branches, and climbs thick branches in manner of a nuthatch (*Sitta*) before moving on to next. **Breeding.** Season May–Jul; usually one brood, but in C Russia (Altai Mts) sometimes two. Monogamous; pairs for life. Territorial; territory occupied throughout year, and may be shared by more than one pair. Display includes courtship-feeding of female by male, which continues to nestling stage. Nest, built by female, a platform of decaying wood, moss, grass stems and animal

hair or fur, placed up to 5 m from ground in hole in rotting tree trunk or stump, often old hole of woodpecker (Picidae); nestboxes used, particularly in areas where natural tree holes absent; territory size apparently large, c. 15–20 ha, or 50–100 ha in marginal or suboptimal habitats (but only small proportion used for breeding). Clutch 4–11 eggs; incubation by female, period 15–18 days; chicks fed by both parents, nestling period 19–20 days; young dependent on adults for up to further 13 days before being abandoned by parents, and then remain together for 3–4 days before dispersing. In N Finland, of 184 eggs, 74% hatched and 60% produced fledglings, average 4.78 young per nest; in second study, of 64 clutches, 72% successful, average 5.9 young per nest; average breeding success in C Finland 6.16 fledged young per breeding pair. Breeds in first year. Longevity at least 7 years; adult mortality at least 49% per year in Finland.

**Movements.** Adults sedentary, remain within territory throughout year. Juveniles, following dispersal from breeding area, are more nomadic (often forming flocks with *P. montanus*), moving between late Aug and Mar up to 200 km S into S Sweden and W & C Siberia; in exceptional years considerable numbers erupt during late Jun–Oct, and has reached S Urals, C Siberia (R Podkamennaya Tunguska) and middle R Amur and, in W, the Baltic coast (e.g. vagrant in Estonia), but, as other irruptive parids, is reluctant to cross large areas of open water. In North America, wanders widely along river valleys.

**Status and Conservation.** Not globally threatened. Common in Siberia, uncommon in Scandinavia and W Russia; rare in Alaska and NW Canada. Estimated European breeding population 164,000–294,000 breeding pairs. In Scandinavia occurs at densities of 0.2–7 pairs/km<sup>2</sup>; in heavily managed forests fewer than 0.5 pairs/km<sup>2</sup>, but density rises to 1.5 pairs where nestboxes available. Has declined in Norway and Finland, largely as a result of changes in forestry management (adversely affecting breeding and foraging areas) and possibly also climatic changes; range in Finland has retreated N by c. 200 km. In extreme N of range, survives severe winters only by complete dependence on food provided at human settlements.

**Bibliography.** Anon. (1983b, 1998a), Armstrong (1991), Bent (1946), Cramp & Perrins (1993), Dementiev *et al.* (1954, 1970), Dixon (1961), Eek (1988), Échécoar & Hûe (1983), Farrand (1985), Flint *et al.* (1984), Gibb (1954, 1960), Gill *et al.* (2005), Godfrey (1986), Haftorn (1973), Hagemeijer & Blair (1997), Hailman & Haftorn (1995), Harrap & Quinn (1996), Harrison (1982), Hartert (1905), Hinde (1952), Johansen (1944), Kaufman (1990), McCarthy (2006), Orell *et al.* (1999), Pyle (1997), Rogacheva (1992), Sibley (2000), Svensson *et al.* (1999), Vaurie (1959), Virkkala (1990).

## 11. Boreal Chickadee

### *Poecile hudsonicus*

**French:** Mésange à tête brune **German:** Hudsonmeise **Spanish:** Carbonero Boreal  
**Other common names:** Hudsonian/Acadian/Brown-capped Chickadee

**Taxonomy.** *Parus hudsonicus* J. R. Forster, 1772, Severn River, Hudson Bay, Canada.

Until recently present genus normally subsumed into a broad *Parus*, and many authors still prefer that treatment. Genus normally treated as feminine, but no evidence in original description or elsewhere justifies this, so genus is masculine by default. Forms a superspecies, and has been considered conspecific, with *P. cinctus* and *P. rufescens*. Geographical variation slight, and confused by seasonal and individual variation; additional named races, based on very slight differences, include *cascadensis* (Cascade Mts, in extreme S British Columbia and extreme N Washington, on SW Canada–USA border), merged with *columbianus*, and *rabbittsi* (described from Newfoundland, in E Canada), synonymized with nominate. Full review of fresh-plumaged individuals of all races required. Five subspecies currently recognized.

#### **Subspecies and Distribution.**

*P. h. stoneyi* (Ridgway, 1887) – NW USA (NC Alaska) and NW Canada.  
*P. h. columbianus* (Rhoads, 1893) – S Alaska and adjacent W Canada, S in NW USA to N Washington.  
*P. h. hudsonicus* (J. R. Forster, 1772) – C Alaska E to E Canada (E to Labrador and Newfoundland).  
*P. h. farleyi* (Godfrey, 1951) – SC Canada (F. British Columbia E to C Manitoba).  
*P. h. littoralis* (H. Bryant, 1865) – extreme SE Canada (S Quebec E to Prince Edward I and Nova Scotia) and extreme NE USA (E from New York).

**Descriptive notes.** 12.5–14.5 cm; 7–12.4 g. Medium-sized, brown-capped and black-bibbed tit with brown upperparts. Nominative race has forehead to crown (including side of crown to below eye) and centre of nape brown, neck side to centre of mantle grey, rest of mantle and upperparts greyish-olive, rump and uppertail-coverts warm buffish-brown; upwinging-coverts as back, lesser and median upwinging-coverts broadly fringed grey; flight-feathers and tail dark grey, finely edged pale grey; lores to eye and slightly over ear-coverts black, cheek white or whitish, becoming greyer on ear-coverts and side of neck; chin

and throat to centre of upper breast sooty black, forming dark bib (with fine whitish tips on sides of throat and along lower border); breast and centre of belly off-white, becoming greyish on side of breast and upper flanks, lower flanks bright cinnamon-brown, undertail-coverts duller or browner; in worn plumage, cheeks duller or dusky, pale fringes of flight-feathers abraded, bib slightly larger and better defined, and rufous on flanks paler or reduced in extent; iris brown; bill black, bluish-grey at base of lower mandible; legs bluish-grey to dark slate-blue. Differs from *P. cinctus* in slightly smaller size, browner crown to back, grey neck side, greyish edges of flight-feathers, and richer cinnamon-brown on flanks. Sexes alike. Juvenile is similar to adult, but crown duller and browner, upperparts also duller or browner, less olive, flight-feather edges dull brownish, bib slightly paler brown and less extensive (not reaching beyond lower throat), warm buff wash on flanks and vent. Races differ relatively little, mainly in size and coloration: *stoneyi* is slightly shorter-billed than nominate, has crown and rump tinged olive-brown, generally lacks pale grey on side of neck; *farleyi* is slightly larger than nominate, has upperparts slightly paler brown, side of neck a little paler grey; *littoralis* is slightly smaller and shorter-billed than nominate, has side of neck dull grey, upperparts somewhat warmer or more olive-brown, rump rufous-brown, flanks dull tawny; *columbianus* has slightly darker upperparts than nominate, some individuals have darker cap and/or darker slate-grey neck side, flanks light tawny-chestnut. **Voice.** Most frequent contact call "dee", "seep" or "up", often given in combination with other notes, e.g. "tsi-tsi-jaaay" or "tsi-tsi-jaaay-jaaay" or "pi-s zer zer, sisi-siu zer zer, chick-chick-char-char", also a harsh "zer-zer" and a sharp "chit" or "chik" as alarm. Song a repetition of the call notes and also sweet, musical, warbling phrases followed by sharp trill "ptwee-tit-tit-tit-tit", but generally silent during breeding season. **Habitat.** Dense lowland conifer forest, usually dominated by stands of spruce (*Picea*) and balsam fir (*Abies balsamea*); in N Alaska limit of range coincides with N limit of white spruce (*Picea*

*glauca*). Also in mixed woodlands including American aspen (*Populus tremuloides*), birches (*Betula*), alder (*Alnus*) and willow (*Salix*) thickets. Often close to bogs or muskeg. Sea-level to above 1525 m in British Columbia and up to 2070 m in Washington; in E of range, between 460 m and 1130 m in New York State.

**Food and Feeding.** Food small invertebrates, larvae and eggs, including moths (Lepidoptera), aphids (Aphidoidea), beetles (Coleoptera) and spiders (Araneae); also some fruit, principally berries of eastern red cedar (*Juniperus virginiana*), also conifer and birch seeds. Stores food mostly in late summer (Jul–Aug), in dead branches, under lichens, in needle clusters, and in deep crevices behind bark (above level of winter snow, but below level affected by blizzards); stored food recovered apparently by chance, rather than by memory. Holds large prey and seeds in foot (or feet), and tears them apart with hammer action of bill. Usually solitary or in pairs in breeding season, but from late summer often in small to medium-sized parties of up to 25 individuals; may join mixed-species flocks with kinglets (*Regulus*). Actively forages among foliage of upper levels of trees, usually in interior of tree, but also among outer foliage and cones at ends of branches; food items taken also from branches and trunk; feeds on the ground principally in spring, when melting snow reveals seeds. Also visits birdtables.

**Breeding.** Season late Apr to mid-Jul; one brood. Monogamous; probably pairs for life. Territorial; previous season's territory usually reoccupied in early spring, not advertised, but defended by singing male when interloper discovered. Courtship includes wing-quivering by female accompanied by begging calls, also feeding of female by male. Nest built solely by female, a pad of moss, lichens, plant fibres, bark strips, animal fur and feathers, placed up to 4–5 m from ground in upward-sloping hole excavated by the pair in tree trunk or stump, or in adapted natural hole or old hole of woodpecker (Picidae); nestboxes also utilized; territory size not well known. c. 5 ha. Clutch 4–7 eggs, occasionally 9; incubation by female, fed by male, period 11–16 days; chicks fed by both sexes, nestling period 15–18 days; young fly at 18 days, dependent on parents for up to a further 21 days. Breeds in first year. Recorded longevity 4 years 8 months.

**Movements.** Resident, and short-distance altitudinal migrant; also cyclically irruptive according to availability of conifer seed crop. Irruptions S, usually to within or just beyond S limits of range, occur between Oct and mid-Apr at intervals of 2–3 years, with larger-scale and longer-distance irruptions (commonly to well S of breeding range) every 6–8 years, often accompanied by similar movement of *P. atricapillus*. In irruptive years occurs S in USA to North Dakota, Wisconsin, Pennsylvania and New Jersey; vagrant S to Wyoming, Nebraska, Iowa, Ohio and Virginia.

**Status and Conservation.** Not globally threatened. Common or locally common; irregularly common in winter or in irruptive years. Densities of 2–11 pairs/km<sup>2</sup> in parts of Canadian breeding range; average of 4–5 pairs/km<sup>2</sup>, peaking with outbreaks of spruce-budworm. Appears to be able to withstand severe spells of extreme weather, e.g. –50°F.

**Bibliography.** Anon. (1983b, 1998a), Armstrong (1991), Bent (1946), Dixon (1961), Farrand (1985), Ficken *et al.* (1996), Gill *et al.* (2005), Godfrey (1986), Harrap & Quinn (1996), Kaufman (1990), McCarthy (2006), Phillips (1986), Pyle (1997), Sibley (2000), Sorrie (1975).

## 12. Chestnut-backed Chickadee

### *Poecile rufescens*

**French:** Mésange à dos marron **German:** Rotrückenneise **Spanish:** Carbonero Dorsicastaño

**Taxonomy.** *Parus rufescens* J. K. Townsend, 1837, forests of Columbia River, probably near Fort Vancouver, Washington, USA.

Until recently present genus normally subsumed into a broad *Parus*, and many authors still prefer that treatment. Genus normally treated as feminine, but no evidence in original description or elsewhere justifies this, so genus is masculine by default. Forms a superspecies, and has been considered conspecific, with *P. cinctus* and *P. hudsonicus*. Nominata race and *neglectus* intergrade widely in area formerly occupied solely by the latter, which considered possibly now swamped by nominate; further research required. Three subspecies recognized.

#### Subspecies and Distribution.

*P. r. rufescens* (J. K. Townsend, 1837) – Alaska, SW Canada and W USA (S to coastal California).

*P. r. neglectus* (Ridgway, 1879) – coastal C California.

*P. r. barlowi* (Grinnell, 1900) – coast of SW California (S from San Francisco Bay).

**Descriptive notes.** 11.5–12.5 cm; 8.5–12.6 g. Small to medium-sized, black-capped and black-bibbed tit with chestnut upperparts. Nominata race has forehead and crown (including side of crown to below eye) and nape sooty brown, slightly darker or blacker on lores, around eye and over ear-coverts; upperparts, including lesser upperwing-coverts, bright chestnut, duller or olive-brown on uppertail-coverts; median upperwing-coverts dark grey, edged chestnut (as upperparts or slightly darker), greater coverts dark grey, fringed paler and tipped whitish; flight-feathers dark grey, tinged brown on tertiaries and secondaries, with

whitish-grey edges (broadest on lower tertial, narrow on inner primaries) forming pale panel on closed wing (usually absent when plumage worn); tail dark grey-brown, broadly fringed dull olive; lower lores, cheek and ear-coverts white to pale buffish-white, chin and throat to neck side and centre of upper breast black, remainder of breast to centre of belly white to dull buffish-grey, breast side and flanks chestnut, becoming duller or browner on vent; iris brown; bill black, with paler cutting edges, pinkish base of lower mandible; legs slate-blue to purplish-grey. Sexes alike. Juvenile is as adult, but crown and bib browner, cheeks duller (not white), and upperparts and flanks more cinnamon-brown, breast and belly greyer. Race *neglectus* is as nominate, but back paler chestnut, greater coverts edged whitish, upper two tertiaries finely fringed rufous, underparts paler grey, and rufous on flanks paler and more restricted; *barlowi* has dull whitish edges on greater coverts, all tertiaries fringed pale rufous, paler underparts, breast side and flanks to undertail pale greyish or tinged olive-brown, with amount of pinkish-buff or dull chestnut greatly reduced. Voice. Calls include frequently given "tsidi-tsidi-tsidi-cheer cheer" or "tsit ti jee jee" or variations, including "chlit-chlit-zee-zee" and "chis-li-zee chis-sli-sli zee zee"; also a deeper or slightly harsher "dee-dee-dee-dee", often given in aggression; other calls include high-pitched "seet", "tsit" or more metallic "tsi-lip" or "tsui-tip", as well as chirruping "chis-li", "chlit chit", "dzui" and "seezi", a musical "swi-swi-swi" or "siu-swee" which may be run into longer phrases, "sizi dzui sizi" or "sizi-dzee-dzee-dzee-dzee-si-dzee". Song appears to be a series of "chi" or "chip" notes on single pitch, "chip-chip-chi-chi-chi-chip", similar to that of Chipping Sparrow (*Spizella passerina*).

**Habitat.** Dense conifer forests, including firs (*Abies*, *Pseudotsuga*), cedars (*Thuja plicata*), hemlocks (*Tsuga heterophylla*), tamaracks (*Larix*) and redwoods (*Sequoia sempervirens*); also plantations,

including Monterey pine (*Pinus radiata*); pine-oak (*Pinus-Quercus*), alder (*Alnus*) and willow (*Salix*) thickets, and scrub; also ornamental trees, including eucalypts (*Eucalyptus*) and cypresses (*Cupressus*) in wooded suburban areas. Prefers woodland edges and borders of rivers or streams. Usually below 915 m, but in USA to up to 1700 m in NW California (Sierra Nevada) and to at least 1830 m in Idaho.

**Food and Feeding.** Food includes small invertebrates and larvae, particularly moths (Lepidoptera), aphids (Aphidoidea), scale insects (Coccoidea), leafhoppers (Cicadellidae), sawflies and wasps (Hymenoptera), spiders (Araneae), crickets (Orthoptera); in non-breeding season also fruits and seeds. Usually in pairs or in small flocks of up to 20 individuals, and occasionally in mixed-species flocks with *P. gambeli*, kinglets (*Regulus*), nuthatches (*Sitta*) and Brown Creepers (*Certhia americana*). Actively and acrobatically forages in foliage of canopy and upper levels of trees, by gleaning among leaves and hanging from slender twigs and branches; also in tangled undergrowth and shrub layer, but rarely descending to the ground. Occasionally pursues passing insects in flight.

**Breeding.** Season mid-Mar to end Jun. Monogamous, apparently pairs for life; one documented case of partners remaining together for four consecutive years. Territorial; occasionally loose colonies of up to seven pairs in close association. Nest built by female, mostly of green moss, animal hair or fur, plant fibres and feathers, placed up to 5 m from ground in cavity in dead branch, tree or stump, hole either excavated by pair or adapted from natural cavity or old hole of woodpecker (Picidae); occasionally in drainpipe, nestbox or disused Cliff Swallow (*Petrochelidon pyrrhonota*) nest; one site used for five years in succession. Clutch 6–8 eggs; incubation by female, period 12–14 days, exceptionally to 18 days; nestling period 18–21 days. Breeds in first year. Recorded longevity 6 years.

**Movements.** Largely resident; small numbers move altitudinally, including post-breeding dispersal to higher elevations in late summer and early autumn. Also, some wander between Nov and Mar, mostly within breeding range but also S to extreme S California; vagrant in Alberta (Canada).

**Status and Conservation.** Not globally threatened. In USA, common to locally common in S Alaska and S California, uncommon in Montana and Idaho; common in Canada. Some range expansion in 20th century in NW & SC California, largely as a result of increase in Douglas fir (*Pseudotsuga*) in mountain forests following cessation of logging and the maturing of orchards and shade trees in areas E of San Francisco; apparently still increasing in S of range.

**Bibliography.** Anon. (1983b, 1998a), Armstrong (1991), Burg (2007), Dahlsten *et al.* (2002), Dixon (1961), Farrand (1985), Gaines (1992), Gill *et al.* (2005), Godfrey (1986), Harrap & Quinn (1996), Kaufman (1990), McCarthy (2006), Pyle (1997), Sibley (2000), Sturman (1968a, 1968b).

## 13. Varied Tit

### *Poecile varius*

**French:** Mésange variée

**German:** Buntmeise

**Spanish:** Carbonero Variado

**Taxonomy.** *Parus varius* Temminck and Schlegel, 1848, Honshu, Japan.

Until recently present genus normally subsumed into a broad *Parus*, and many authors still prefer that treatment. Genus normally treated as feminine, but no evidence in original description or elsewhere justifies this, so genus is masculine by default. Has hybridized with *P. montanus*. Geographical variation largely clinal, grading progressively smaller and darker from N to S. Birds from Yakushima (off S Japan) described as race *yakushimensis*, supposedly slightly darker on forecrown and side of head than those on neighbouring Tanegashima, but differences considered insufficient to warrant separation from *sunsunpi*. Eight subspecies recognized.

#### Subspecies and Distribution.

*P. v. varius* (Temminck & Schlegel, 1848) – S Kuril Is, Japan, NE China (SE Liaoning, S Jilin) and Korea.

*P. v. sunsunpi* (Nagamichi Kuroda, 1919) – Osumi-shoto (Tanegashima, Yakushima), off S Japan.

*P. v. namiyei* (Nagamichi Kuroda, 1918) – N Izu Is (Toshima, Nijima, Kozushima).

*P. v. owstoni* (Ijima, 1893) – S Izu Is.

*P. v. amamii* (Nagamichi Kuroda, 1922) – NC Ryukyu Is (Amami-oshima S to Okinawa).

*P. v. olivaceus* (Nagamichi Kuroda, 1923) – Iriomote, in S Ryukyus.

*P. v. castaneiventris* (Gould, 1863) – Taiwan.

*P. v. orii* (Nagamichi Kuroda, 1923) – Daito-jima (Borodino Is).

**Descriptive notes.** 12–14 cm; 15.9–18.2 g. Medium-sized, black-capped tit with grey upperparts and chestnut underparts. Male nominate race has forehead buffish, crown (including crown side down to eye) and nape black, slightly glossy on crown, sometimes a narrow yellowish-buff or whitish patch on hindneck; upper mantle chestnut (forming narrow band), rest of upperparts, including upperwing, deep greyish-blue, flight-feathers fringed narrowly paler grey; tail blackish, broadly fringed greyer; lores, cheek and ear-coverts pale buffish-white to off-white, usually slightly whiter on side of neck; chin and

throat to lower neck side black (sometimes flecked with rufous tips), centre of upper breast below bib whitish or light buff, belly and vent whitish-buff, flanks rufous-chestnut, undertail-coverts light cinnamon; iris very dark red to blackish-cinnamon; bill dark brown or black; legs dark grey. Female resembles male but slightly smaller on average, and paler or more buffish on breast side and flanks. Juvenile is a duller version of adult, crown to nape paler or greyer with extensive white tips, upperparts tinged grey-brown, greater coverts tipped pale buff to rufous-buff, tertiaries and secondaries fringed greyish-olive, lores, cheeks and ear-coverts buffish or yellowish, chin to breast smudged greyish, underparts mostly dull or dingy whitish, side of breast and flanks less extensively rufous than on adult, vent and undertail-coverts smudged with grey. Race *sunsunpi* is as nominate, but upperparts slightly darker grey, and breast side and flanks deeper chestnut; *amamii* differs from nominate in having slightly larger bill, chestnut on upper mantle reduced or absent, rest of mantle duller grey and washed olive, also duller chestnut on underparts; *olivaceus* is like previous, but slightly more heavily washed olive above; *castaneiventris* is similar to both of previous two and smaller than nominate, with chestnut on upper mantle restricted, lacks olive tinge on upperparts, and has entire underparts uniformly deep chestnut; *orii* has extensive area of chestnut on upper mantle, upperparts more clearly tinged olive, forecrown, head side and entire underparts deep chestnut; *owstoni* is similar to last but darker, has forehead to cheeks and neck side rufous, lower nape orange-rufous, upperparts greyish-tinged olive, underparts entirely cinnamon-rufous, darkest on breast and flanks; *namiyei* is intermediate between last race and nominate, cheek colour highly variable, from very pale buff to brick-brown. Voice. Calls include weak "tsuu tsuu tsuu" as contact, a thin, sharp "pit" or "chit", more drawn-out and high-pitched "spu-see-see-see" and scolding

“chi-chi-chi” or stuttering “stt-ti-ti-ti...”; also a variable “dza” to more prolonged “dzecu” in series as “dzer-dza-dza-dzer-dzer” notes, or in combination with “chit” or “stitz” as “stitz tit-dzer, stit-tit-dzer”, or may conclude with “dza-dza-dza”. Song, in Japan mostly between Mar and Jun, a repetition of monotone or variable whistles, usually including ringing “peee” as in “tsre-tsre peee-triri-peee-triri-peee-triri”; race *owstoni* recorded as giving “chip, tuwee, chip-chip-tuwee, chip-chip-tuwee”, but full range of geographical variation in song not fully studied; may also give faint but melodious subsong in Japan.

**Habitat.** Lowland conifer forests, particularly of yew (*Taxus*) in Kuril Is, and open deciduous and mixed forests in China and Taiwan; in Japan prefers mature deciduous, mixed and evergreen broadleaf forests, usually with dense undergrowth or shrub layer, also found in plantations mainly of cedar (*Cedrus*) and cypress (*Cupressus*, *Chamaecyparis*). Usually avoids urban areas or villages, but in Japan and Korea occurs in woodland areas around shrines (including in centre of Tokyo) and not infrequently in well-wooded large gardens. Principally in lowlands or hills, to c. 1100 m on Taiwan and in Korea; to c. 1600 m in S Japan, but generally below 1000 m in N Honshu. In S China, birds recorded in Guangdong were at c. 1200 m.

**Food and Feeding.** Food mostly small invertebrates, including spiders (Araneae); also seeds and nuts (principally of *Castanopsis cuspidata* and *Styrax japonica*) and berries, including those of yew. Food, principally nuts, stored in autumn and used to sustain birds through the following winter, also as food for young in following breeding season. Fairly shy and often elusive; usually solitary or in pairs, but in autumn and winter may form small parties or join mixed-species flocks. Forages mostly in upper and canopy levels, by gleaning prey from among foliage, and also from large branches and from tree trunks; not uncommonly feeds also at lower levels and in undergrowth. Occasionally pursues insects in flight.

**Breeding.** Season early Mar to Aug; possibly two broods in S of range. Pairs for life. Territory defended throughout year. Nest built mostly by female, mostly of moss and plant fibres, placed up

to 6 m from ground in natural hole or cavity in tree or old stump, or pair may excavate hole or utilize old hole of woodpecker (Picidae); also uses (but less frequently prefers) nestboxes, and cavities under eaves of buildings. Clutch 6–7 eggs on Japanese mainland, slightly fewer (on average, 4–6) on S islands; incubation by female, period 12–14 days; nestling period 17–21 days; young dependent on parents for further 21 days, thereafter semi-independent but may be fed by parents for up to 80 days further. Breeding success in nestboxes on Kozushima, in N Izu Is (race *namiyei*), very poor: of 51 nests monitored, 83% failed to produce any young, main cause of failure being predation by snakes.

**Movements.** Largely resident. Some may move altitudinally or make local and relatively short movements in Japan (principally Hokkaido) and Korea, where small numbers on passage in late Apr and May and Oct–Nov, but present throughout year in N of range. Apparently only vagrant on Sakhalin I, where two birds recorded in 1976, though it could perhaps be a sporadic breeder.

**Status and Conservation.** Not globally threatened. Common or locally very common to abundant in S Japan and Kuril Is; uncommon in N Japan (Hokkaido and N Honshu), local on Taiwan, and rare in NE China. In Daito-jima (race *orii*) now presumed extinct, as not found in surveys in 1984 and 1986 or subsequently. In Japan, densities in evergreen forest 1–3 pairs/km<sup>2</sup> to 5–6 pairs/km<sup>2</sup> in S Honshu, and 10–15 pairs/km<sup>2</sup> in Izu Is. Introduced and apparently established in Hawaii Is (on Kauai and Oahu), but not seen since 1963. In SE China, individuals of unknown race recorded on Ba Bao Shan (S Guangdong), but proximity to Hong Kong suggests possibility of escapes from captivity. This species is one of the three most popular cagebirds in Japan, and traditionally taken for use in fortune-telling; effects of cagebird trade on wild populations not known.

14. Black-breasted Tit

*Periparus rufonuchalis*

**French:** Mésange à nuque rousse    **German:** Fichtenmeise    **Spanish:** Carbonero Nuquirrofo  
**Other common names:** Rufous-naped/Rufous-vented/Black-crested/Dark Grey/Simla Black Tit

**Taxonomy.** *Parus rufonuchalis* Blyth, 1849, Simla, north-western Himalayas, India. Until recently present genus normally subsumed into a broad *Parus*, and many authors still prefer that treatment. Occasionally considered conspecific with *P. rubidiventris*. Birds from Afghanistan E to N Pakistan (Gilgit) have been proposed as warranting racial separation (as *blanchardi*), but differences from populations elsewhere appear inconstant. Monotypic.  
**Distribution.** S Uzbekistan, Tajikistan and Kyrgyzstan, SW China (W Xinjiang), NW & E Afghanistan, W & N Pakistan and E in Himalayas to WC Nepal (Kali Gandaki gorge).

**Descriptive notes.** 13 cm; 11.4–14.7 g. Medium-sized to large, dark tit with short peaked crest and bright white cheeks. Male has forehead to crown and crest black or slightly glossy blue-black, small whitish nuchal patch with lower edge buff or warm buff-brown (purer white in N Pakistan); cheek and ear-coverts white; upperparts dark grey, tinged lightly olive (mantle paler grey in E Afghanistan and N Pakistan); tail similar to upperparts, all rectrices finely fringed paler or bluish-grey; upperwing-coverts dark grey, fringed bluish-grey; flight-feathers blackish-grey, finely fringed bluish-grey; chin and throat (including side of throat) to breast and upper belly black, side of lower breast, upper flanks and axillaries rufous or light cinnamon (often visible at bend of wing), lower belly and lower flanks grey, undertail-coverts light rufous to cinnamon (paler and more buff in N Pakistan); iris brown; bill black; legs lead-grey to black. Differs from *P. rubidiventris* in larger size, more extensive black bib (reaching to upper belly) and grey (not rufous) lower belly; from *P. melanolophus* also in having uniform wings. Female is very like male, but on average has less gloss on crown and duller, less extensive black on breast and upper belly. Juvenile is similar to adult, but crown and crest duller or dark grey, crest also shorter, nape patch dull whitish, upperparts more clearly washed brownish-olive (but tail and wings as adult), cheeks washed faintly buffish, chin to breast smudged blackish, rest of underparts dull grey-brown, paler buff on undertail-coverts. Voice. Calls include plaintive “cheep” or “peep” and short “sip”, often in combination as e.g. “sip-sip-sip, pee-sip, sih-pee, puu-sih-pu, tu-si-si”, also low-pitched, sharp “chut” or “chut-chut” and rapid “trrrr” similar to that given by *Parus major*. Has two songs: one (for establishing and marking territory) a series of up to 6 whistled notes followed by rapid trill or buzz, “tip tip-pee-trrrrrrr”, sometimes with other whistles added at end; the other song (in territory defence) a variable series of whistled notes followed by downslurred whistle, “tsi-tsi-peeduw”, or “whi-when, pitch-uu” reminiscent of some songs of *P. ater*, or a loud and slightly slower “tju-tju-hee”.

**Habitat.** Montane and submontane conifer forests, principally of spruce (*Picea*), fir (*Abies*), deodar (*Cedrus deodara*) and pine (*Pinus*). In W of range (E to NW Himalayas) most frequently found in junipers (*Juniperus*), and in C Himalayas extends into spruce-oak (*Picea-Quercus*), birch (*Betula*) and rhododendrons (*Rhododendron*); occurs also in more open areas of scattered scrub and trees on hillsides. In NW Pakistan also in poplars (*Populus*), willows (*Salix*) and edges of cultivation, particularly mulberries (*Morus*) and in hazel (*Corylus*) scrub. Breeds at 1800–3000 m in C Asia and Afghanistan, 2200–3700 m in N Pakistan and N India, 2400–4000 m in W Nepal, and 2900–3500 m in NW China; in non-breeding season also at lower levels, down to 1200–1500 m in C Asia, down to 2100 m but exceptionally to foothills at c. 760 m in N Pakistan, and down to 1500 m elsewhere in Himalayas.

**Food and Feeding.** Food mostly small invertebrates, seeds and berries; nestlings fed entirely with insects and larvae. Uses cracks in bark or branches as regular ‘anvils’ in which it places seeds and nuts, opening these by hammering them rapidly with the bill; not known to store food. Usually solitary, in pairs in breeding season; may join small mixed-species foraging flocks, often including *P. melanolophus*. Forages at all levels, from tops of trees to undergrowth, and frequently on ground.

**Breeding.** Season Apr–Jul. Monogamous. Display by male includes drooping and quivering of half-opened wings, hopping around female while emitting soft twittering notes. Nest built by both sexes, mostly of moss, animal hair or fur, wool and feathers, male adding material while female incubating, placed deep within hole or cavity low down (less than 1 m from ground) in tree trunk or stump, or in hole in wall, or frequently on ground in hole in steep bank, under stones or among roots of tree. Clutch 4–6 eggs; incubation by female, chicks fed by both parents; no information on duration of incubation and nestling periods.

**Movements.** Largely resident; appears very well adapted to extremely cold winters at high elevations, but small numbers descend to lower levels outside breeding season.

**Status and Conservation.** Not globally threatened. Common in N India, and fairly common in Nepal; elsewhere in range locally common, but uncommon in W China.

**Bibliography.** Ali & Ripley (1983), Cheng Tsohsin (1987), Dementiev *et al.* (1954, 1970), Échécopar & Hûe (1970, 1983), Fleming *et al.* (1979), Flint *et al.* (1984), Gill *et al.* (2005), Grimmer *et al.* (1998), Harrap & Quinn (1996), Hartert (1905), Hûe & Échécopar (1970), Inskipp & Inskipp (1991), Jamdar & Price (1990), King *et al.* (1975), MacKinnon & Philipps (2000), Martens (1971), Martens *et al.* (2006), Rasmussen & Anderton (2005), Roberts (1992), Stuart Baker (1932), Vaurie (1959).

15. Rufous-vented Tit

*Periparus rubidiventris*

**French:** Mésange cul-roux    **German:** Rotbrustmeise    **Spanish:** Carbonero Culirrofo  
**Other common names:** Rufous-bellied Crested Tit, Black Crested Tit; Sikkim Black Tit (*beavani*)

**Taxonomy.** *Parus rubidiventris* Blyth, 1847, Nepal.

Until recently present genus normally subsumed into a broad *Parus*, and many authors still prefer that treatment. Occasionally treated as conspecific with *P. rufonuchalis*. Race *beavani* not known to interbreed with nominate and has been considered to represent a separate species; further research required. Marginally paler birds with different wing proportions from NC China (NE Qinghai) are genetically different and probably better separated as race *whistleri*; those of W Sichuan similar to previous but possibly further separable as slightly darker race *szetschwanensis*. Three subspecies provisionally recognized.

**Subspecies and Distribution.**

*P. r. rubidiventris* (Blyth, 1847) – W & C Himalayas from Kashmir E to C Nepal.  
*P. r. beavani* (Jerdon, 1863) – E Himalayas, C & SW China (Qinghai E to S Shaanxi, S to S Xizang, W Yunnan and N & W Sichuan) and NE Myanmar.  
*P. r. saramatii* (Ripley, 1961) – NE India (Nagaland) and adjacent NW Myanmar (Mt Saramati).

**Descriptive notes.** 12–13 cm. 7–13.1 g. Small to medium-sized, compact tit with black cap and pointed crest, rufous underparts. Male nominate race has forehead to crown and crest black or slightly glossed bluish, small nuchal patch white with faint rufous tinge; cheek and ear-coverts whitish; upperparts dark grey, lightly tinged olive, except for more buffish uppertail-coverts; tail similar to back, all rectrices finely fringed bluish-grey; upperwing-coverts dark grey, fringed bluish-grey; flight-feathers blackish-grey, finely fringed bluish-grey, palest on inner primaries; chin and throat (including side of throat) to upper breast

black, rest of underparts light rufous (deeper on belly) or rufous-buff, except for greyish lower breast side and flanks; in worn plumage, crown duller, upperparts darker and underparts duller; iris blackish-brown to reddish-brown; bill black; legs lead-blue to blue-grey. Differs from *P. rufonuchalis* mainly in smaller size, less extensive black on breast, and rufous belly to undertail-coverts; from *P. melanolophus* in having darker coloration, rufous underparts, no white tips on wing-coverts. Female is very like male, but on average slightly paler on crown and duller on chin to upper breast. Juvenile is similar to adult, but crown and blunt-tipped crest duller, nape patch dull whitish, upperparts washed buffish, cheeks washed buffish-yellow, chin to breast smudged dull brownish-black and contrasting very little with rest of dull grey underparts, undertail-coverts dull buff. Racial variation well marked: *beavani* has nuchal spot off-white or buffish, cheeks washed buffish, upperparts more heavily tinged bluish-grey (not olive), grey lower breast becoming greyish-buff on belly and flanks, undertail-coverts deep cinnamon, juvenile darker above than nominate and with yellowish cheeks and ear-coverts, adults in N of range (NE Qinghai) slightly paler on mantle and uppertail-coverts and paler rufous on belly; *saramatii* has upperparts washed buffish-olive, richest buff on rump, underparts dull olive-grey. Voice. Calls include thin high-pitched “seet” or “seep” and clearer or more silant “pseet”, “pee” or “piu” and “psit”, together with softer “pwit” or “whit”, also sharp “chip”, “chit” or “tip”, all of which may be given in longer combined series, e.g. “seep-seep, seep-seep sip-ti, pseet-seep, tip-pee, tip-piu-sweep, tip-piu-chip”, or may vary combinations with stuttering “ch-ch-ch-ch” series or longer variation of “chip-sweep” notes; alarm includes scolding “chit-it-it-it...” and rapid “tsit-tsit-tsit-tsit, tsweep”, also “whid-ip” or “whid-id-ip”. Song mid-Mar to mid-Jun, varies geographically, in W of range (nominate race) a rattling series of up to 30 “chi-chi-chi” or “chip-chip-chip-chip” or “sfrit-chut-chut” notes, with rapid delivery of up to 10 notes per second; in E combines the rattle with whistled notes at varying pitches, either pure or downslurred, e.g. “tu-toodle-toodle-toodle-toodle-ut” and ringing “seet-cha-weet”, also slower, musical trilling “schip-it, schip-it, schip-it”, repeated frequently.

**Habitat.** Forests, mostly deciduous, principally oak (*Quercus*), and mixed broadleaf forest and woodland, to mixed forests of pine (*Pinus*), hemlock (*Tsuga*), cypresses (*Cupressus*, *Chamaecyparis*), rhododendron (*Rhododendron*), birch (*Betula*), fir (*Abies*), juniper (*Juniperus*) and dwarf willow (*Salix*); breeds in rhododendron forest in NE India (Nagaland). Also visits high-altitude rhododendron and treeless scrub. Breeds at 3000–4100 m in W Himalayas, 2550–4250 m (possibly regularly to 4575 m) in Nepal, 2745–4270 m in E Himalayas, from 2500 m to tree-line in China, and at 2745–3660 m in N Myanmar. In non-breeding season, also temperate oak forests at lower elevations, down to c. 2400 m in W Himalayas, to c. 2100 m in Nepal and slightly higher in E Himalayas, at 2800–3200 m in Bhutan, but many remain at high levels throughout winter, e.g. recorded at 4270 m in Feb in Nepal and at 2440–3050 in NE Qinghai (China).

**Food and Feeding.** Diet poorly known; presumably includes small invertebrates and larvae, and some seeds. Usually in pairs or in groups of up to 20, including during breeding season; also in mixed-species foraging flocks (but rarely associates with other parids) in non-breeding season. Forages mostly in canopy and upper levels of forest trees, but also descends to lower levels and undergrowth.

**Breeding.** Poorly known. Season Apr–Jun in Himalayas. Nest mostly of moss and animal fur, placed up to 6 m from ground in hole or cavity in tree, or in hole in ground in bank or among roots of tree. Clutch 2–3 eggs. No further information.

**Movements.** Resident, with some altitudinal movements to lower levels in non-breeding season.

**Status and Conservation.** Not globally threatened. Generally common in Himalayas and in SW China (SE Xizang), although less numerous to uncommon in W Himalayas; common in C China and locally common in N Myanmar. Situation in Kashmir and NW India unclear, but species is apparently a very scarce breeder there.

**Bibliography.** Ali & Ripley (1983), Cheng Tsohsin (1987), Échécopar & Hûe (1983), Fleming *et al.* (1979), Gill *et al.* (2005), Grimmer *et al.* (1998), Harrap & Quinn (1996), Hartert (1905), Hûe & Échécopar (1970), Inskipp & Inskipp (1991), Jamdar & Price (1990), King *et al.* (1975), MacKinnon & Philipps (2000), Martens & Eck (1995), Martens *et al.* (2006), Meyer de Schauensee (1984), Rasmussen & Anderton (2005), Robson (2000), Smythies (1986), Spierenburg (2005), Stuart Baker (1932), Vaurie (1959), Wolters (1980a).

16. Spot-winged Tit

*Periparus melanolophus*

**French:** Mésange de Vigors    **German:** Schwarzschoepfmeise    **Spanish:** Carbonero Crestinegro  
**Other common names:** Crested Black Tit, Black-crested Tit, Spot-winged Black Tit, Vigors’s Tit

**Taxonomy.** *Parus melanolophus* Vigors, 1831, Simla–Almora district, Himalayas, north India.

Until recently present genus normally subsumed into a broad *Parus*, and many authors still prefer that treatment. Forms a superspecies with *P. ater*, and the two regularly hybridize in W Nepal; sometimes considered conspecific. Birds from NE Afghanistan and adjacent Pakistan, slightly larger and with darker upperparts than those elsewhere in species' range, may merit subspecific recognition; further research required. Monotypic.

**Distribution.** E Afghanistan, NW Pakistan and Himalayas E to WC Nepal.

**Descriptive notes.** 11–12 cm; 7–9.8 g. Small to medium-sized slaty-grey tit with pointed black crest. Has forehead to crown (including crown side down to eye) and crest, nape and upper mantle black or glossy blue-black, white nuchal patch; cheek and ear-coverts pure white; lower mantle and rest of upperparts bluish-grey with light olive tinge (darker grey at W end of range); tail dark brownish-grey, all feathers finely fringed paler or bluish-grey; upperside-coverts blackish-grey, broadly fringed bluish-grey, tips of median and greater coverts whitish with rusty-buff outer edge, alula and primary coverts blackish, in fresh plumage finely

fringed blue-grey; flight-feathers dark brown to blackish, narrowly fringed bluish-grey, secondaries and primaries sometimes finely tipped white; chin and throat (including side of throat) to upper breast black, upper flanks bright rufous to cinnamon (may extend narrowly to lower flanks), lower breast, belly, lower flanks and vent grey (individuals with cinnamon-orange on belly and vent considered hybrids), undertail-coverts light rufous or cinnamon-buff; axillaries light cinnamon (often restricted to bend of wing); in worn plumage, crest slightly shorter or blunt-tipped, crown less glossy, upperparts less bluish, pale tips of wing-coverts abraded and whiter, edges of flight-feathers worn or abraded, bib duller or browner, underparts also duller; iris brown; bill black; legs lead-grey to dark bluish-grey. Differs from both *P. rufonuchalis* and *P. rubridiventris* in smaller size, broad white wingbars on tips of wing-coverts and smaller bill, from former also in having less black on breast and from latter in having grey (not rufous) belly; differs from *P. ater* mainly in darker mantle, rufous on breast side and flanks, dark grey belly. Sexes alike. Juvenile is similar to adult, but crown and crest duller, crest also shorter, nape patch dull whitish or fringed brownish, upperparts (including upper mantle) more clearly washed olive-brown, tips of median and greater upperside-coverts often more extensively rusty buff and forming complete wingbars, inner tertials tipped buffish, cheeks washed faintly buffish, chin to breast dark brown, sometimes greyer on lower throat and breast, and duller grey on rest of underparts except for paler buff undertail-coverts. **VOICE.** Calls frequently; many calls closely similar to those of *P. ater*, include thin "tsit" or "stii", occasionally as more emphatic "psip" or "pip" or more explosive "chziou" or "piu", often combined in longer series of "pip-chziou, pip, pip-sziu..." or "pet-chew, pet-chew", together with lower-pitched, plaintive 3-note "tsi-tsu-whichoo, tsi-tsu-whichoo", and high-pitched or squeaky "si" which may be run into longer "sisisi"; has been recorded as giving snake-like hiss when defending nest. Song a repetition of "psip-iu..." and "chip-wi", similar to that of *P. ater*.

**Habitat.** Breeds in montane and submontane conifer forests, including pine (*Pinus*), deodar (*Cedrus deodara*), fir (*Abies*), spruce (*Picea*) and juniper (*Juniperus*), usually with shrub layer of rhododendron (*Rhododendron*); at 1500–3000 m in Afghanistan, 1800–3200 (perhaps to 3660 m) in N Pakistan, 1525–3355 m (locally to 3700 m) in NW & N India, and 2800–4000 m in Nepal. In non-breeding season also in oak (*Quercus*), willows (*Salix*) and hazel (*Corylus*) groves in open scrubby areas with scattered conifers; in Pakistan recorded in foothills down to 600 m, exceptionally to 370 m or lower, including in gardens in large cities (Islamabad, Rawalpindi) and plains of R Indus in Feb; many, however, remain at high altitude throughout winter, including at 2400 m in N Pakistan and at 2955 m in Kashmir when deep snow still lying.

**Food and Feeding.** Food consumed is not well known, but includes small invertebrates, larvae, seeds, and berries and other fruit; takes sunflower (*Helianthus*) seeds from gardens. Usually in pairs or in varying sized groups throughout year; in autumn up to 80 together, and during winter flocks of 50 (30–40 still together in Apr); also joins mixed-species foraging flocks containing other parids, small warblers (Sylviidae), Goldcrests (*Regulus regulus*), Eurasian Treecreepers (*Certhia familiaris*) and other insectivores. Actively and restlessly forages in lower to middle levels of conifers, searching through foliage, examining twigs and cones and hovering on outer edges, in spring also in canopy of deciduous trees. At all times may forage at lower levels in shrub layer or on ground.

**Breeding.** Season Apr to early Jul; one brood. Monogamous. Nest consists of moss, animal fur, wool and/or hair, placed up to 3 m (exceptionally to 15 m) from ground in natural hole or cavity in tree trunk or stump, less frequently in hole in wall (including of inhabited house) or bank. Clutch 5–6 eggs, exceptionally 10; incubation by female, fed on nest by male, period 14–15 days; chicks fed by both parents, nestling period up to 21 days.

**Movements.** Resident, or makes short-distance post-breeding descent to lower levels.

**Status and Conservation.** Not globally threatened. Common to abundant; the commonest tit throughout most of W Himalayas E to W Nepal.

**Bibliography.** Ali & Ripley (1983), Bates & Lowther (1952), Fleming *et al.* (1979), Gill *et al.* (2005), Grimmett *et al.* (1998), Harrap & Quinn (1996), Hartert (1905), Hüb & Échécopar (1970), Inskipp & Inskipp (1991), Martens & Eck (1995), Martens *et al.* (2006), McCarthy (2006), Paynter (1962), Rasmussen & Anderton (2005), Roberts (1992), Stuart Baker (1932), Vaurie (1959).

## 17. Coal Tit

### *Periparus ater*

**French:** Mésange noire

**German:** Tannenmeise

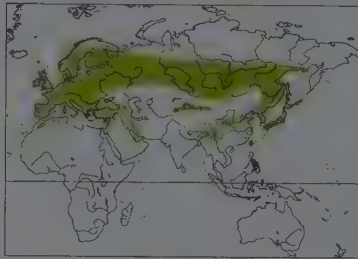

**Spanish:** Carbonero Garrapinos

**Taxonomy.** *Parus ater* Linnaeus, 1758, Sweden.

Until recently present genus normally subsumed into a broad *Parus*, and many authors still prefer that treatment. Forms a superspecies with *P. melanolophus*, and the two regularly hybridize in W Nepal; sometimes considered conspecific. Known to have hybridized also with *Poecile montanus*, *Lophophanes cristatus* and *Parus major*. Geographical variation well marked but complicated by high degree of local and individual variation within populations; furthermore, races intergrade in parts of range; ongoing genetic research suggests presence of a series of regional clusters across range. Additional proposed races are *pinicolus* (described from Scotland), synonymized with *britannicus*; and *abietum* (from W & C mainland Europe), *rossosibiricus* (C Russia from Moscow E to about L Baikal) and *amurensis* (Amurland, Ussuriland, Sakhalin), all merged with nominate. Recently described *ekodendricatus* (Gansu, Sichuan, Shaanxi, N Yunnan) morphologically almost identical to *aemodius*; probably merits separation, on basis of genetic differences. Twenty-one subspecies currently recognized.

#### Subspecies and Distribution.

- P. a. britannicus* (Sharpe & Dresser, 1871) – Great Britain and extreme NE Ireland.  
*P. a. hibernicus* (Ogilvie-Grant, 1910) – Ireland.  
*P. a. ater* (Linnaeus, 1758) – N, C & E Europe, W & S Asia Minor, N Syria and Lebanon, and Siberia E to Sakhalin, and S to Altai, N Mongolia, NE China (Manchuria E to E Liaoning) and Korea.  
*P. a. vieirae* (Nicholson, 1906) – Iberian Peninsula.  
*P. a. sardus* (O. Kleinschmidt, 1903) – Corsica and Sardinia.  
*P. a. atlas* (Meade-Waldo, 1901) – Morocco.  
*P. a. ledouci* (Malherbe, 1845) – N Algeria and NW Tunisia.  
*P. a. moltchanovi* (Menzies, 1903) – S Crimea.  
*P. a. cypristes* (Dresser, 1888) – Cyprus.  
*P. a. derjugini* Zarudny & Loudon, 1903 – SW Caucasus S to NE Turkey.  
*P. a. kichalowskii* (Bogdanov, 1879) – Caucasus (except SW) and C & E Transcaucasia.  
*P. a. gaddi* Zarudny, 1911 – SE Azerbaijan and N Iran.  
*P. a. chorassanicus* (Zarudny & Bilkevitch, 1911) – SW Turkmenia and NE Iran.  
*P. a. phaenotus* (Bianford, 1873) – SW Iran (Zagros Mts).  
*P. a. rufipictus* (Severtsov, 1873) – C & E Tien Shan from extreme SE Kazakhstan E to extreme NW China (W Xinjiang).  
*P. a. martensi* (Eck, 1998) – Kali Gandaki valley, in C Nepal.  
*P. a. aemodius* (Blyth, 1845) – E Himalayas (from C Nepal), C China (S Gansu & S Shaanxi S to S Xizang and NW Yunnan) and N & E Myanmar.  
*P. a. pekinensis* (David, 1870) – E China (S Liaoning S to N Shanxi, Hebei and Shandong).  
*P. a. kuatunensis* (La Touche, 1923) – E China (S Anhui S to NW Fujian).  
*P. a. insularis* (Hellmayr, 1902) – S Kuril Is and Japan.  
*P. a. ptilosus* (Ogilvie-Grant, 1912) – Taiwan.

**Descriptive notes.** 10–12 cm; 7.2–12 g. Small, slim-billed, black-crowned tit (some races crested) with greyish upperparts and two wingbars. Male nominate race has forehead to crown (including crown side down to eye) and nape black, tinged bluish (in Balkans–W Turkey and in extreme SE Russia and Sakhalin, can possess a short, ragged crest), large white nuchal patch; cheek and ear-coverts white; upperparts deep bluish-grey (slightly paler blue-grey in Russia E to about L Baikal), tinged lightly olive-brown, more prominently brown to olive on rump and uppertail-coverts; tail dark grey-brown, all feathers finely fringed

paler or greyish-olive; upperside-coverts blackish-grey, broadly fringed bluish-grey, tips of median and greater coverts white, alula and primary coverts blackish, the latter fringed finely blue-grey (in fresh plumage); flight-feathers grey-brown, tertials finely fringed greyer and broadly tipped white, secondaries and primaries finely fringed grey or olive-grey, inner secondaries finely tipped white; chin and throat (including throat side) to side of upper breast black, breast and belly white, flanks to vent and undertail-coverts greyish to light cinnamon-buff; axillaries and underwing-coverts light buffish-white; in worn plumage, white nuchal patch can show some dark bases, upperparts duller or darker bluish-grey, pale fringes and tips of wing-coverts abraded and greyer, edges of flight-feathers worn or abraded, cheeks dingier, underparts also duller, dirty white on breast and belly and greyish-buff on flanks to vent; iris brown or dark brown; bill black, paler grey sides; legs lead-grey to dark bluish-grey. Female is similar to male but female has crown slightly less glossy, crown, mantle and scapulars a shade more greenish, wing-coverts duller or fringed greyer, and chin to upper breast brownish-black. Juvenile is similar to adult, but crown and nape sooty grey, nuchal patch smaller and more yellowish-white, upperparts dark grey with brownish or greenish-olive wash, median and greater coverts fringed dark grey and tipped off-white, flight-feathers as adult or fringed greenish or olive, cheeks washed pale yellow, chin to breast dark brown or greyer, rest of underparts yellowish except for pale buff flanks and undertail-coverts. Races differ mainly in depth and tone of plumage coloration: *britannicus* is as nominate, but in fresh plumage cheeks, ear-coverts and nape patch creamy white, upperparts greyish olive-buff and less bluish, edges of remiges and rectrices olive (and white tip only on upper tertial), bib slightly less extensive, flanks to vent and undertail-coverts pale rufous-buff to cinnamon-buff (paler when worn), variable, in Scotland upperparts olive-grey and flanks to undertail-coverts brownish-buff ("pinicolus"); *hibernicus* resembles previous, but upperparts dull greenish-olive (less buff), cheeks, ear-coverts, nape patch and underparts pale yellow (whiter when worn) except for warm buff to cinnamon-buff flanks and undertail-coverts, bib patch of female smaller; *vieirae* is as nominate, but upperparts washed olive-brown, flanks buffish-brown, tendency for juveniles to have larger area of sooty-brown bib; *sardus* is as nominate, but upperparts washed olive-brown in fresh plumage (slightly less olive-brown than previous), flanks to undertail-coverts pale buffish-brown; *atlas* is similar to nominate, but upperparts dull greyish-green, cheeks, ear-coverts and nape patch yellowish-white, bib slightly more extensive than other races (reaching to upper breast), lower breast and centre of belly yellowish-white, flanks deep buffish-grey; *ledouci* resembles last, but upperparts green with greyish-olive wash (slightly duller and greyer on female), cheeks, ear-coverts, nape patch, lower breast and belly washed pale yellow, flanks olive-grey; *moltchanovi* is similar to nominate, but bill slightly larger, mantle slightly paler blue-grey, underparts also paler, belly, flanks and undertail-coverts whitish; *cypristes* has black on head more extensive (white face patch more restricted), reaching to upper mantle, upperparts rich brown, tips of median coverts warm buff, edges of remiges and rectrices brownish, larger bib extending to centre of breast, breast to centre of belly pale pinkish-buff, flanks and lower underparts rufous-brown; *derjugini* has longer wing and bill than nominate, mantle slightly browner or greyer and lightly tinged olive, flanks to undertail-coverts light sepia-brown or greyer; *kichalowskii* is as nominate, but mantle and scapulars paler olive-brown, and flanks to undertail-coverts washed pale buffish; *gaddi* resembles last, but mantle and scapulars richer or darker brown, and flanks to undertail-coverts also washed darker buff-brown; *chorassanicus* is similar to previous, but mantle paler grey, tinged sandy brown; *phaenotus* is also similar to *gaddi*, but darker or more cinnamon-brown above, and has paler underparts, with buff on flanks to undertail-coverts; *rufipictus* is similar to nominate, but has short erect black crest, mantle slightly duller and greyer, tips of median coverts buffish or yellowish, tips of greater coverts pale buffish-white, also duller below, breast and belly pale pinkish-buff, flanks to undertail-coverts warm buffish-brown or buffish-tan, juvenile lacks crest, has crown and bib browner (bib often has smudged lower edge), yellowish wash on cheeks and ear-coverts, upperparts more olive-tinged; *aemodius* is as last, but has longer crest, paler underparts, extensively clear pinkish-buff on breast and belly; *martensi* is similar to last but slightly larger, has darker mantle and back, and underparts more reddish-ochre, except for grey flanks; *pekinensis* resembles nominate, but has short crest, buff wash on cheeks, ear-coverts and nape patch, olive wash on mantle, and paler underparts with

flanks greyer; *kuatunensis* is similar to previous, but has longer crest, nape patch nearly white, blue-grey upperparts faintly tinged olive on back, cheeks tinged pale buff, and underparts creamy buff with flanks greyish; *ptilosus* is very similar to last, but crest longer, upperparts slightly darker, and generally whiter or less buffish on underparts; *insularis* is as nominate, but tips of median upwing-coverts buffish, and underparts paler or more creamy to cream-buff. Voice. Calls include distinctive, mellow or plaintive "pui" or "tsuee" and variations with differing emphasis, including "sih", "sui" and "tsueueet", sometimes combined with other notes and run into longer phrases e.g. "swee-pi, sui-pi", and may conclude with drawn-out twitter; also thin "sisisi" similar to high-pitched note of Goldcrest (*Regulus regulus*), and especially in C Asia a more rapid "chit, chipippip" similar to that given by both *Parus major* and *Cyanistes caeruleus*; alarm notes include repeated series of sharp "pwee" or "peeh" notes, sometimes combined with series of harsher or more hoarse "szee", "zee" or "eez"; adults (usually mostly female) and feathered young give drawn-out hissing, similar to that of other parids, when predator in vicinity of nest; in N Africa, seemingly uniquely, a low churring or trilling "trrrrrrr" alarm. Song, in Mar–Sept, a 2-note or 3-note phrase repeated several times at varying speed and emphasis, "teehuu, teechuu", "tchuee-tchuee" or "chippie chip-pe", "peechee-peechee-peechee", "tu-wa-chi tu-wa-chi", "chi-chi-chi", "pe-twi pe-twi" and the like, also a more slurred but rhythmic "sit-tui, sit-tui, sit-tui". Male has up to 16 song types, each varying slightly from others, and these can be given in same song period or different ones given from one perch to another; little geographical variation, although on Cyprus (race *cypriotes*) song considered to be lower-pitched and slightly slower and includes some buzzing notes; female also sings, usually less loudly than male, but unaccompanied females can equal male.

**Habitat.** Conifer forests, mainly (in parts of range almost exclusively) in spruce (*Picea*), also mixed forest, often dominated by birch (*Betula*), and in pine (*Pinus*) and larch (*Larix*) in Siberia. In S Europe, Caucasus and NW Iran mostly in Aleppo pine (*Pinus halepensis*) or Calabrian pine (*Pinus brutia*), montane beech (*Fagus*) and oak (*Quercus*) forests, and in NW Africa mainly in junipers (*Juniperus*), cedars (*Cedrus*) and oaks, including holm oak (*Quercus ilex*), cork oak (*Quercus suber*) and zeen oak (*Quercus faginea*), also holly (*Ilex*), pines and gum juniper (*Tetraclinis articulata*); in Iran occurs locally also in high-altitude junipers. In C Asia, Himalayas and N China occurs in spruce, fir (*Abies*), hemlock (*Tsuga*) and birch and above tree-line in dwarf junipers, but in SC China more often in pines; in Europe often in conifer plantations and in urban and suburban areas with small numbers of conifers. In non-breeding season often in similar habitat, but also more frequently in deciduous woodland, parks and gardens. Breeds throughout much of W Palearctic from sea-level to c. 1800 m, exceptionally to 2050 m, but only above 500 m in Caucasus and above 1250 m in S Bulgaria, and in NW Africa at 1000–2500 m in Middle and High Atlas (Morocco); in N Iran occurs at 1220–2135 m; 2440–4000 m in NE Indian Subcontinent (exceptionally, to 4250 m in Nepal), 2745–3445 m in N Myanmar, 1220–2745 m in NW China, 2100–4570 m in SW China, and 800–1800 m in NE China and Korea; mostly at 600–2550 m in Japan but occurs down to sea-level on Hokkaido, and in Taiwan resident between 2000 m and 3500 m. In Himalayas, winters between 1800 m and 3810 m.

**Food and Feeding.** Food adult and larval bugs (Hemiptera), including aphids (Aphidoidea), also beetles (Coleoptera), lacewings (Neuroptera), flies (Diptera), caddis flies (Trichoptera), moths (Lepidoptera), damselflies (Odonata), bush-crickets (Orthoptera), bees and wasps (Hymenoptera), ants (Formicidae), spiders (Araneae), harvestmen (Opiliones), mites (Acari), millipedes (Diplopoda), centipedes (Chilopoda), slugs and small molluscs, and small earthworms (Oligochaeta); also seeds, preferentially of spruce (but often not available owing to unpredictability of cone crop), fir, pine, yew (*Taxus*), juniper, larch, redwood (*Sequoia*), cypress (*Chamaecyparis*), Japanese cedars (*Cryptomeria*), beech, sycamore (*Acer pseudoplatanus*), rowan (*Sorbus*), hornbeam (*Carpinus*), alder (*Alnus*), birch, walnut (*Juglans*), oak; also buds and catkins of willow (*Salix*), hazel (*Corylus*) and aspen (*Populus*), and sap of aspen, birch and maple (*Acer*). Regularly visits birdtables and feeders, where it takes nuts, seeds and household scraps, and has learnt to pierce or open milk-bottle tops to take cream. Size of insect prey usually up to c. 2–3 mm, exceptionally 6–7 mm, but caterpillars of 14 mm fed to nestlings. Diet of nestlings similar to that of adult but fewer seeds; in years of high caterpillar abundance these can form entire diet of nestlings, but generally fewer caterpillars in pine forest, where relies mainly on spiders. Seeds and hard-shelled insects rapidly and repeatedly stabbed with bill to remove outer husk or shell before softer parts eaten or taken for storage; also holds seeds in foot while tearing off outer layer. Stores food, mostly spruce seeds (or invertebrates when spruce seeds not available), between Jun and Dec (possibly also Apr), in lichen and bark crevices and holes in upper parts of trees and in base of hedges or holes in ground; cached food utilized in times of hard winter weather, but in parts of range only small part of winter diet is from stored food; at study sites recovery of stored food variable, from none at all to accidental refinding or considerable dependency, differing according to location and to severity of winter. Occurs alone, in pairs or in loose groups of pairs, and in non-breeding season highly social and often in fairly large groups of up to 50 individuals, more exceptionally flocks of hundreds or thousands recorded in Siberia; also joins mixed-species foraging flocks, which frequently include *Lophophanes dichrous*, *P. rufonuchalis*, Eurasian Treecreeper (*Certhia familiaris*), Goldcrest (*Regulus regulus*) and leaf-warblers (*Phylloscopus*). Actively and acrobatically forages mostly in upper levels of conifer trees, often perching on or hanging from cones and vertical needle clumps while extracting seeds with its fine bill, also flutters and hovers while gleaning insects from the outside of foliage; in deciduous trees more often examines branches, twigs and leaves (including undersides) for concealed insects; may also climb trunk vertically, and pursue slow-flying insects in flight. Frequently forages on ground, usually for fallen seeds and fruits of beech, sweet chestnut (*Castanea*) and oak; on snow-covered ground may forage in areas exposed by squirrels (Sciuridae) and wild pigs (*Sus*).

**Breeding.** Season end Mar to late Jul, later in N of range than in S; frequently two broods (though rarely so in deciduous woods), occasionally three, but only one in Corsica and N Africa. Monogamous, with lifelong pair-bond; members of one pair recorded together for 6 years. Territorial. Pair formation and display involve prolonged periods of wing-shivering and wheezing calls and slow gliding flight by male, with wings and tail fully spread, passing close to partner, followed by lengthy courtship feeding. Nest built by female alone, cup-shaped, made almost entirely of moss, some animal hair, wool and some feathers incorporated, placed in hole or cavity (usually with very narrow entrance) in tree trunk or old stump, including abandoned hole of rodent or woodpecker (Picidae), sometimes in hole or crevice in wall or rocks, in ground under stones, among roots of fallen tree or in mouse (Muridae) hole; holes in trees not usually excavated by pair but may be enlarged; nestbox occasionally used; size of territory not well studied but possibly small, radius c. 100 m in optimum habitats. Clutch 5–13 eggs, generally fewer in W Mediterranean, S & SE Asia and Japan, second clutches also smaller; incubation by female, period 14–16 days; chicks brooded by female, fed by both parents, nestling period 18–22 days, in Japan sometimes shorter (c. 16 days); recently fledged young remain together in thick cover for first few days out of nest, in contrast to behaviour of most other parids (young of which follow adults). Breeding success generally high: in studies in Germany, Corsica and Turkey, ratios of young fledged as percentage of eggs laid were 88–5% in spruce forest, 82% (first broods) and 87% (second broods) in larch plantations, 73% in cedar woodland, 57% in evergreen oak woodland, 78% in mixed woodland; ratios of young fledged as percentage of young hatched were 98% (first broods) and 99% (second broods)

in Scots pine (*Pinus sylvestris*), 92% (first broods) and 100% (second broods) in Corsican pine (*Pinus nigra*) and 99% in broadleaf woodland; loss of young to natural causes (other than predation) small compared with broods of *Parus major* and *Cyanistes caeruleus*. Breeds in first year.

**Movements.** Resident or makes short-distance altitudinal movements in S & W of range; N & E populations move longer distances, and occasionally irruptive. In British Is moves short distances, with very few recoveries at more than 20 km (most less than half this distance). Adults in Scandinavia and C Europe chiefly resident, but juveniles regularly migrate S or SW between late Aug and early Nov, mostly to S France and N Italy; in years when seed crop poor or fails, these S movements become much larger, often involving numerous large flocks totalling thousands of individuals (e.g. 35,000 at Hanko Bird Observatory, in S Finland, and more than 18,700 at Falsterbo, in S Sweden), usually during late Aug to early Oct; ringing studies reveal that flocks involved in these movements may travel up to 60 km per day, and may coincide with similar large-scale movements of *Poecile montanus* and Long-tailed Tits (*Aegithalos caudatus*); in irruption years some reach S & E coasts of British Is, and exceptionally NE Spain and Morocco; return passage movements usually Apr–May, occasionally into Jun. In W Russia may completely desert breeding area in some years and be present throughout (including in N parts) in others; small numbers also move N in autumn into N taiga forest and edges of tundra on shores of Arctic Ocean and Taymyr Peninsula, e.g. one ringed in Kaliningrad (W Russia) in Oct recovered 2000 km ENE in following Apr; similar pattern around Vladivostok, in SE Russia, with some present throughout year and small numbers moving S in Oct–Nov and returning mid-Mar to May. In NE China, regular autumn passage migrant at Beidaihe in Oct–Nov; in Korea (nominate race) and Japan (*insularis*) primarily altitudinal migrant, but *insularis* largely absent from Hokkaido (N Japan) in winter, when more numerous in Honshu and also at least occasional visitor to NE coast of China and Taiwan. Race *aemodius* a seasonal altitudinal migrant in Himalayas. Vagrant in Israel.

**Status and Conservation.** Not globally threatened. Common or fairly common in much of range; locally common in N Myanmar, and uncommon or scarce in Turkmenistan, Mongolia and SE China; recently discovered breeding in N Syria. SW Iranian race *phaenotus* either very rare or, possibly, extinct; has not been seen since it was originally discovered, in 1870. European breeding population between 13,000,000 and 27,000,000 pairs. Breeding densities variable, depending on habitat and, sometimes, on abundance of nestboxes; up to 50 pairs/km<sup>2</sup> in Scots pine plantation in E England, and twice that in optimum habitat elsewhere in Europe; in C Siberia, occurs at densities of 124–138 birds/km<sup>2</sup> in pine woods. Some expansion of range in NW Europe within 20th century, principally into W Scotland (Outer Hebrides), W Ireland, Scilly Is, Channel Is and W France; at same time has increased numerically in Britain, Belgium, Netherlands and Hungary, largely as a result of large-scale increase in commercial forestry plantations. In S Germany, small decline in numbers in spruce forest in Harz Mts owing to large-scale reduction in aphids and spiders caused by industrial pollution and acid rain.

**Bibliography.** Ali & Ripley (1983), Barnes (1975), Brazil (1991), Brown & Grice (2005), Cheng Tsohsin (1987), Cramp & Perrins (1993), Dementiev *et al.* (1954, 1970), Eck (1998), Échécopar & Hùe (1967, 1983), Fleming *et al.* (1979), Flint *et al.* (1984), Fry *et al.* (2000), Gibbons *et al.* (1993), Gill *et al.* (2005), Glutz von Blotzheim & Bauer (1993), Grimmett *et al.* (1998), Hagemeijer & Blair (1997), Handrinos & Akriotis (1997), Harrap & Quinn (1996), Harrison (1982), Hartert (1905, 1921), Hollom *et al.* (1988), Hùe & Échécopar (1970), Inskipp & Inskipp (1991), Johansen (1944), King *et al.* (1975), Lee Woo-Shin *et al.* (2000), Löhrl (1974), MacKinnon & Philipps (2000), Martens & Eck (1995), Martens *et al.* (2006), McCarthy (2006), Meyer de Schauensee (1984), Murdoch (2005b), Perrins (1979), Porter *et al.* (1996), Rasmussen & Anderton (2005), Robson (2000), Rogacheva (1992), Smythies (1986), Snow (1955), Spierenburg (2005), Stepanyan (1990), Stuart Baker (1932), Svensson *et al.* (1999), Tomek (2002), Vaurie (1959), Wernham *et al.* (2002).

## 18. Yellow-bellied Tit

### *Periparus venustulus*

**French:** Mésange gracieuse **German:** Schmuckmeise **Spanish:** Carbonero Ventrigualdo

**Taxonomy.** *Parus venustulus* Swinhoe, 1870, gorges of Yangtze between Kweifoo (Sichuan) and Ichang (Hubei), east China.

Until recently present genus normally subsumed into a broad *Parus*, and many authors still prefer that treatment. Alternatively, has been combined with *P. elegans* and *P. amabilis* in a separate genus, *Pardaliparus*, and may form a superspecies with these two. Monotypic.

**Distribution.** EC & E China from NE Hebei S to S Gansu, C & E Sichuan and NE Yunnan, and from W Hubei S to NW Guangxi and E to S Anhui, C Hunan, N Jiangxi and N Guangdong; non-breeding also coastal districts from Jiangsu S to S Guangdong.

**Descriptive notes.** 10–11 cm; 9–12.5 g. Small tit with large head and short tail; black cap and bib and bright yellow underparts. Male has lores, forehead to crown (including crown side down to eye), nape and side of upper mantle black (crown glossed blue), long white nuchal patch variably extending to centre of upper mantle; cheek and ear-coverts to neck side pure white; centre and lower sides of mantle, scapulars and back bluish-grey, rump similar or slightly paler and greyer, longest rump feathers tipped olive-green, uppertail-coverts black, central feathers tipped olive-green; tail blackish-grey, narrowly fringed pale grey and finely tipped white, all rectrices except central pair with long segment of white on outer web towards base (amount of white increasing towards outermost feather); lesser upwing-coverts blackish-grey with thin glossy bluish fringe, median and greater coverts black, tipped white (greater sometimes with fine dark olive-green fringes), alula white with yellowish fringe; flight-feathers dark grey to blackish, secondaries and tertials finely fringed yellowish or yellowish-olive, tertials also tipped white or off-white (secondaries and primaries also finely tipped white in fresh plumage); chin and throat (including side of throat) to upper breast black (throat may be tipped yellowish or white in fresh plumage), rest of underparts yellow, slightly paler on undertail-coverts, washed olive on flanks; iris dark brown; bill black to bluish-black; legs lead-grey. Female is similar to male but generally duller, forehead and crown dull bluish-grey with darker centres (mottled appearance), side of crown also darker or greyer, sometimes a short and narrow pale line over and behind eye, nape grey with yellowish-white nuchal patch, mantle and scapulars olive-green, becoming greyish-olive on back and bluish-grey on rump, uppertail-coverts greyish, tipped bluish-grey; tail and wings as male, but lesser and median coverts edged olive-green and white tips of medians washed yellowish, edges of flight-feathers slightly more green than on male; cheek and ear-coverts off-white, narrow greyish malar stripe connecting with same colour on neck side; chin and throat white, underparts as male but slightly duller. Juvenile is similar to female but sexes separable at

early age: young male has forehead to crown, nape and upperparts olive-green, very short (and often indistinct) supercilium over eye, broad dark eyestripe and blackish nape side, pale yellow spot on centre of nape, duller or yellowish-tinged cheeks and ear-coverts, indistinct greyish malar stripe, pale yellow chin and throat, dull yellowish side of neck; juvenile female as juvenile male but has paler wings and tail, with tips of median and greater coverts tinged yellowish, cheeks and ear-coverts dingy yellowish-white, malar stripe poorly defined. **Voice.** Calls include thin and fairly soft "sit-oo", rapid and high-pitched "si-si-si-si", and frequently uttered nasal 3-note "dzee dzee dzee" which also extended into more varied "sip-eeh, sip, zee-zee-zee". Song mostly a series of single or disyllabic and rather metallic notes repeated in short phrases, "swi-swi-swi, suwi-suwi-suwi, sipu-sipu-sipu", or occasionally interspersed with more complex phrases, e.g. "spid-i-chu-sp-id-i-chu...", "wee-wa-chi, wee-wa-chi, wee-wa-chi...", "psi-wed-i, psi-wed-i, psi-wed-i" and similar.

**Habitat.** Broadleaf subtropical and evergreen forests, including mixed conifer and deciduous forest with bamboo, larches (*Larix*), willow (*Salix*) groves and other scattered trees at edges of cultivation; in non-breeding season more widely dispersed and may be found in almost any sizeable patch of trees. In summer at 1200–1500 m around Beijing, 500–2500 m in S Shaanxi, 600–2700 m in Sichuan, 350–1600 m in Guizhou and to 3050 m in S Gansu; outside breeding season usually below 1000 m, including on plains and near coast in E of range.

**Food and Feeding.** Diet not well known, but includes small invertebrates, larvae and seeds; known to store food, but details lacking. Usually in pairs or in small groups of up to four individuals (probably family parties); in non-breeding season gathers in higher numbers, with up to 30 recorded in single flock, and also joins mixed-species foraging flocks. Forages at middle to low levels in trees and undergrowth.

**Breeding.** Poorly known. Season at least May–Jun. Nest mostly of green moss, leaves, plant fibres, wool and animal hair, placed in natural hole or cavity in base of tree or among rocks, or in bank. Clutch 5–7 eggs; incubation by female, for up to 12 days; chicks fed by both sexes, nestling period 16–17 days; young become semi-independent after further 3 days.

**Movements.** Resident and altitudinal migrant; descends to lower levels in Nov–Apr non-breeding season. Appears to be an erratic or irruptive visitor in S & E, from Jiangsu S to Guangdong, with influx years followed by years with none at all. In recent years, recorded annually as a migrant at Beidaihe, on Gulf of Bohai (coastal NE Hebei), late Apr and May and late Sept to late Nov.

**Status and Conservation.** Not globally threatened. Locally common to rather uncommon. Considered to have declined as a result of large-scale forest clearance in China; reported as common in NW Fujian in mid-1920s, but not found there in summer 1986; uncommon also in NW Jiangxi in extensive area of forest still remaining. Recent records of regular passage in NE Hebei suggest that the species probably breeds also to the N of currently known range.

## 19. Elegant Tit

### *Periparus elegans*

**French:** Mésange élégante

**German:** Panthermeise

**Spanish:** Carbonero Elegante

**Taxonomy.** *Parus elegans* Lesson, 1831, Manila, Luzon, Philippines.

Until recently present genus normally subsumed into a broad *Parus*, and many authors still prefer that treatment. Alternatively, has been combined with *P. venustus* and *P. amabilis* in a separate genus, *Pardaliparus*, and may form a superspecies with these two. Described race *panayensis* (from Panay) possibly merits recognition; tentatively included in nominate, although bird forms from Panay are normally closest to Negros forms; further research required. Nine subspecies currently recognized.

#### Subspecies and Distribution

*P. e. edithae* (McGregor, 1907) – extreme N Philippine Is (Calayan, Camiguin Norte).

*P. e. montigenus* (Hachisuka, 1930) – NW Luzon, in N Philippines.

*P. e. gilliardi* (Parkes, 1958) – Bataan Peninsula, in WC Luzon.

*P. e. elegans* (Lesson, 1831) – EC & S Luzon, Mindoro, Catanduanes and Panay.

*P. e. albescentis* (McGregor, 1907) – C Philippines (Ticao, Masbate, Guimaras, Negros).

*P. e. visayanus* (Hachisuka, 1930) – Cebu, in SC Philippines.

*P. e. mindanensis* (Mearns, 1905) – EC & S Philippines (Samar, Leyte, Mindanao).

*P. e. suluensis* (Mearns, 1916) – Sulu Archipelago (except Bongao).

*P. e. bongaoensis* (Parkes, 1958) – Bongao I, in W Sulu Archipelago.

black, median and greater wing-coverts broadly tipped white, alula narrowly edged whitish, tertials broadly tipped white, secondaries and primaries finely tipped white (on outer webs only); chin and throat (including side of throat to below cheek) to side of upper breast black, forming bib, lower edge of which tipped pale yellow; rest of underparts yellow, paler on undertail-coverts, and rear flanks tinged greyish; axillaries and underwing-coverts white, fringed pale yellow; in worn plumage, crown less glossy, upperparts paler or whitish, pale fringes and tips of flight-feathers abraded, bib duller; iris reddish-brown to dark brown; bill black, bluish-grey base; legs pale blue-grey to dark bluish-slate. Female is similar to male, but crown slightly less glossy, nuchal patch smaller and duller yellow, mantle and scapulars greenish-grey and broadly spotted brownish-black (or with occasional yellowish-white spots on mantle), pale tips of tail smaller, upwelling-coverts duller and white tips smaller, flight-feathers fringed olive-grey; cheek to ear-coverts and neck side paler and duller, bib slightly smaller and browner, and underparts paler yellow. Juvenile male is similar to adult, but crown greyer, darker on side of crown and on upper nape and on nape side, nuchal patch smaller and dull yellowish-white, upperparts greenish-grey, scapular edges spotted darker, lores and cheeks dull yellow, becoming whiter on ear-coverts, short dark malar stripe, lacks dark bib, has underparts dingy yellow, lower mandible pale yellowish; juvenile female similar, but forehead and crown greyish-brown, nuchal patch small or poorly defined, usually larger dark spots on

scapulars, wingbars tinged yellowish, less white on tips of tertials, face dull yellowish, lacks malar stripe. Races well marked: *edithae* is as nominate but longer-billed, mantle blacker with reduced white spots, back and rump greenish-grey, cheeks, ear-coverts and nuchal spot white, underparts duller yellow; *montigenus* differs from nominate in having nuchal patch longer (extending to upper mantle), white spots on mantle smaller, underparts paler yellow, female more extensively greenish-grey (with fewer dark centres) on upperparts; *gilliardi* is as nominate, but male has nuchal patch, cheeks, ear-coverts and underparts deeper yellow, upperparts more broadly yellow (fringed blackish on mantle and scapulars), larger white tips on wing-coverts, tertials and rectrices, female very similar to male and with bib nearly as dark, but mantle and back tinged browner, tips of wing-coverts tinged yellowish, edges of primaries greenish-yellow; *albescentis* has large nuchal patch and upper mantle white, rest of mantle and scapulars broadly pale greyish-white, back and rump pale grey with yellow tinge, larger white tips of wing-coverts, tertials and secondaries, uniformly pale yellow underparts, female similar but with yellowish spots on upperparts (on Negros, male may have yellow wash on spots on back and rump, and female has crown paler, greater-covert fringes olive-green, smaller white tips of wing-coverts and tertials, flight-feathers fringed yellowish-olive, and bib slightly paler, not so black); *visayanus* differs from nominate in having more heavily spotted back, fewer spots on wings, dark greenish-grey flanks, female similar but greyer on flanks; *mindanensis* has nuchal patch yellow, mantle, back and scapulars blackish, heavily tipped or washed yellow, back and rump olive-yellow, wing spots and tail spots edged yellow, flight-feathers edged yellow or olive-yellow, female similar but cap sooty brown and extending to side of mantle, tips of wing-coverts and rectrices smaller, flight-feathers fringed olive-green, bib dark olive-green, underparts yellowish with olive-green wash; *suluensis* is similar to previous, but has greenish upperparts and grey-green scapulars, reduced yellowish spots on mantle (absent on female), slightly deeper yellow underparts; *bongaoensis* is as last, but male has mantle and back blacker, slightly fringed greenish, white tips of wing-coverts and rectrices smaller, flight-feathers fringed greenish. **Voice.** Calls include short "sit" or "sit-sit", thin "sisisi", and light and occasionally prolonged trilling "siiiiilililil", fading towards end; also a nasal "chay" and "si-si-si-tzee-tzee" and a series of mellow whistles, "twi-wi-wi-wi-wi-wi, tui-tui-tui-tui-tui"; on Luzon most frequent call an alternating "tweeet chuck-z-chuck-z-chuck-z", and on Mindanao race *mindanensis* gives more monotonous "sweet, sweet, sweet, sweet, sweet" or occasionally an alternating "chi-bow sweet-zee-sweet-zee-sweet-zee"; on Negros, call of *albescentis* a rapid "sweet-zee-sweet-zee-sweet-zee-zoo". Song "pi-tu, pi-tu, pi-tu", or longer and more complex variations on same theme, e.g. "pi-pi-tu, si-si pi-pi-tu, pi-pi-yu, si-si-si pi-pi-pi-tu"; also, apparently, a warbling song with muffled and buzzing trills, reminiscent of a canary (*Serinus*).

**Habitat.** Dense primary evergreen forest, including pine (*Pinus*) forest and moss forest, also edges of secondary forest and scattered trees at edges of cultivation. Lowlands to c. 2480 m.

**Food and Feeding.** Diet not well known, but includes small invertebrates and larvae, seeds, some fruit. Usually in pairs or in small groups of up to eight individuals; may join mixed-species foraging flocks with *Phylloscopus* warblers, fantails (*Rhipidura*) or Velvet-fronted Nuthatches (*Sitta frontalis*). Actively forages in middle to lower levels of forest trees and at canopy level in smaller trees and bushy shrubs.

**Breeding.** Poorly known. Adults in breeding condition in Jan–Jun, carrying nest material in Mar–Apr, and fledging in Apr and juveniles in Mar–Nov on Luzon, and juveniles in Apr and Oct on Mindanao. Nest includes moss, placed in hole or in hollow tree. No other information.

**Movements.** Resident.

**Status and Conservation.** Not globally threatened. Common or fairly common. Appears able to persist in suboptimal habitats.

**Bibliography.** Amadon & duPont (1970), Curio (1994), Delacour & Mayr (1945), Dickinson *et al.* (1991), Gill *et al.* (2005), Gilliard (1950), Gonzales & Sicala (1969), Hachisuka (1930), Harrap & Quinn (1996), Kennedy *et al.* (2000), Martens *et al.* (2006), Mearns (1916), Parkes (1958, 1963), duPont (1971), Ripley & Rabor (1958), Worcester & Bourns (1898).

## 20. Palawan Tit

### *Periparus amabilis*

**French:** Mésange de Palawan

**German:** Kapuzenmeise

**Spanish:** Carbonero de Palawan

**Other common names:** Black-headed Tit

**Taxonomy.** *Parus amabilis* Sharpe, 1877, Balabac, Philippines.

Until recently present genus normally subsumed into a broad *Parus*, and many authors still prefer that treatment. Alternatively, has been combined with *P. venustus* and *P. elegans* in a separate genus, *Pardaliparus*, and may form a superspecies with these two. Monotypic.

**Distribution.** Calauit, Palawan and Balabac, in W Philippines.

**Descriptive notes.** 12–13 cm. Medium-sized tit with all-black head and bright yellow underparts. Male has entire head to nape, neck side, throat and upper breast glossy black, mantle, back and scapulars bright lemon-yellow, rump blue-grey, and uppertail-coverts black with deep indigo-blue gloss; tail black, all feathers tipped white, outer web of outer three pairs distally white; lesser upwelling-coverts black, medians white, and greater black at bases but broadly white on distal half of feathers; alula and primary coverts black, finely tipped white, flight-feathers blackish or blackish-brown, tertials tipped white and fringed yellowish-white, secondaries and primaries finely tipped white (more broadly on secondaries), secondaries narrowly fringed pale grey; underparts from lower breast bright deep yellow, becoming paler on undertail-coverts, flanks washed olive; iris brown or dark brown; bill black; legs grey. Female is similar to male, but hood browner, narrow pale yellow collar on lower nape and side of neck, mantle and scapulars greenish-olive, back grey, rump bright yellow, usually less white in tail, lesser coverts dark grey, white on median and greater coverts reduced, tips of greater coverts more yellowish-white, underparts duller. Juvenile male is similar to adult female, with head and face olive-brown, small pale yellow nuchal spot, upperparts uniformly dull olive (no yellow collar), wing-coverts fringed olive or olive-green, wingbars also narrow (confined to feather tips) and yellowish, dark bib only faintly indicated, bill paler than adult; juvenile female differs from male in having tail browner, secondaries fringed yellowish-green. **Voice.** Calls frequently, and more often heard than seen; range includes thin "sit sisi", rapid and fairly harsh and repetitive "chuiwi-chuiwi-chuiwi-chuiwi...", "wichi-wichi-wichi-wichi" and similar, also accelerating rattle of repeated "wich-chi-chi-chi-chi-chi", an alternating "zuweet zuweet zuweet zuweet zuweet" or slightly more musical "tui-tui-tui-tui-tui", and a descending trill, "srlilililil". Song a repeated series of disyllabic "ti-da" notes, very like similar note of *P. ater*.

**Habitat.** Forests, including secondary forest, edges of swamps and cultivation, in lowlands and submontane regions.

**Food and Feeding.** Diet not well known, but includes small invertebrates and larvae, seeds, some fruit. Usually solitary, in pairs or in small groups; may join mixed-species flocks. Actively and conspicuously forages in canopy to middle levels of forest trees, and occasionally lower, to undergrowth and bushy shrubs; less frequently in scrub.

**Breeding.** Birds in breeding condition in May. No other information.

**Movements.** Resident.

**Status and Conservation.** Not globally threatened. Currently considered Near-threatened. Restricted-range species: present in Palawan EBA. Uncommon. Introduction of logging activity on the largely untouched island of Palawan raises concern for the species' long-term survival. Occurs in St Paul Subterranean River National Park.

**Bibliography.** Anon. (2006f), Butchart & Stattersfield (2004), Delacour & Mayr (1945), Dickinson *et al.* (1991), Gill *et al.* (2005), Hachisuka (1930), Harapp & Quinn (1996), Kennedy *et al.* (2000), Martens *et al.* (2006), duPont (1971), Stattersfield & Capper (2000).

Genus *LOPHOPHANES* Kaup, 1829

21. European Crested Tit

*Lophophanes cristatus*

**French:** Mésange huppée      **German:** Haubenmeise      **Spanish:** Herrerillo Capuchino  
**Other common names:** Crested Tit

**Taxonomy.** *Parus cristatus* Linnaeus, 1758, Sweden.

Until recently present genus normally subsumed into a broad *Parus*, and many authors still prefer that treatment. Relationship with *L. dichrous* uncertain; further study needed. Both were previously considered, on grounds mainly of morphology, to have close affinity with *Baeolophus wollweberi*. Has hybridized with *Periparus ater*. Geographical variation largely clinal; races *weigoldi*, *abadiei* and *mitratus* intergrade widely in W Europe; *baschkirikus* and *buresschi* are poorly differentiated from nominate, and considered by some to fall within range of variation of latter. Seven subspecies recognized.

**Subspecies and Distribution.**

*L. c. scoticus* Prazák, 1897 – NC Scotland.

*L. c. abadiei* (Jouard, 1929) – W France.

*L. c. weigoldi* (Trazt, 1914) – W & S Iberia.

*L. c. cristatus* (Linnaeus, 1758) – N & E Europe S to Carpathian Mts.

*L. c. baschkirikus* Snigirewski, 1931 – SW & C Urals.

*L. c. mitratus* (C. L. Brehm, 1831) – C Europe S to NE Spain, Alps, Croatia and N Serbia.

*L. c. buresschi* (Jordans, 1940) – Albania E to Bulgaria, and N & C Greece.

**Descriptive notes.** 11.5–12 cm; 9.7–15.8 g. Small to medium-sized, crested tit with black-and-white face pattern. Male nominate race has forehead to crown and short spiky crest black with broad white feather fringes (creating scaled appearance), fringes narrower on base of crest (crest shorter and fringes absent in worn plumage); narrow vertical black line on nape connecting with blackish collar on upper edge of mantle; upperparts mostly cold grey-brown, slightly warmer on uppertail-coverts and paler or greyer on upperwing-coverts; alula and flight-feathers dark grey to blackish, primaries finely edged grey; tail brownish-grey.

finely fringed grey-brown, outer web of outermost feather edged white; supercilium (flaring behind eye to include side of hindcrown), cheek, ear-coverts and neck side white, sometimes lightly washed buff, black eyestripe (indistinct in front of eye and not reaching base of bill) and rear edge of ear-coverts; chin, throat and centre of upper breast black, this narrowing at side to join with black line along upper mantle; rest of underparts mostly white, light buffish-grey on breast side, flanks and undertail-coverts; iris variably pale brown to deep red; bill black; legs olive-grey to bluish-grey. Female is very like male (and sexes not separable in the field), but has, on average, shorter crest, narrower stripes on head side, more buffish (less white) feather fringes on crown and crest, and more buff on flanks. Juvenile is very similar to adult, but has browner crown and shorter crest with more rounded tips, side of head washed buffish, eyestripe and rear edge of ear-coverts browner and less well defined, upperparts duller, bib browner with some whitish feather tips and not connected laterally to side of upper mantle. Racial variation slight: *baschkirikus* is very similar to nominate but paler and greyer, and faintly creamy (not buff) on flanks; *buresschi* is very like both nominate and previous, but has slightly duller and darker upperparts, yellowish flanks; *mitratus* differs from nominate in having upperparts cinnamon-brown (browner and greyer individuals also occur), rump and uppertail-coverts warmer brown with pinkish tinge, edges of wing-coverts and tail feathers cinnamon-brown, edges of flight-feathers grey-brown, off-white below, belly washed buffish, rest of underparts washed brownish-cinnamon; *scoticus* is similar to previous, but with dull fringes on forehead and crown, slightly duller or darker brown (not cinnamon) upperparts, also duller below, flanks and undertail-coverts washed browner; *weigoldi* resembles last, but pale fringes on head top broader and whiter (creamy on female), upperparts paler or greyer and less olive, underparts somewhat whiter; *abadiei* differs from last in having feather tips of forehead and crown washed buffish, cheek washed buffish, upperparts rich brown with rufous tinge, rump brighter orange-cinnamon, underparts strongly washed buff, flanks brighter cinnamon. **VOICE.** Most frequent call a thin, rising "zee-zee-zee-cheera-cheera" followed by low, tremulous purring "brrrrrr, t-brrrrrr...", introductory notes variable, sometimes "zizizi", "sizi-za, sizi-za, sizi-za" or a lighter "si-si-si-sisissisi" declining towards end; also a thin "see", singly or in series, and squeaky "sith, sith, silililili". Song a longer and louder version of the "tsee-tsee-tsee burrrrrl, burrrrrl" notes, variably introduced with high-pitched "seeh-i-" notes, and rapidly and frequently repeated.

**Habitat.** In N Europe occurs in stands of pine (*Pinus*) and spruce (*Picea*), mainly Norway spruce (*Picea abies*), also often in conifers in mixed woodland; in Scotland apparently confined to stands of old (more than 20 years) Scots pine (*Pinus sylvestris*) with some deciduous trees, principally birch (*Betula*) and alder (*Alnus*); in Belgium favours mature tall spruces and old pines, avoided by other parids. In C, S & SW Europe found in wider variety of habitats, including open woodland

with well-developed ground layer or shrubs and with good numbers of decaying trees and stumps (for nest-sites); in beech (*Fagus*) forest in Pyrenees, and in cork oak (*Quercus suber*) in S Iberia. In W Russia mostly in spruce and pine forests, avoiding broadleaf and mixed forests. In SE Europe favours high-altitude conifer forests, mostly of Norway spruce, also Greek fir (*Abies cephalonica*) and black pine (*Pinus nigra*). In non-breeding season may make short-distance movements to forage in areas of shrubby juniper (*Juniperus*) or heather (*Erica*, *Calluna*); locally, also in parks and orchards, and visits gardens. Occurs up to tree-line, to 615 m in Scotland; largely montane in S Europe, to 1800 m in Austria and at 1000–2300 m in Balkans and N Greece.

**Food and Feeding.** Food mostly small invertebrates and their larvae, and in non-breeding season seeds and some fruits. Invertebrate diet includes damselflies and small dragonflies (Odonata), stoneflies (Plecoptera), mayflies (Ephemeroptera), bugs (Hemiptera) including aphids (Aphidoidea), lacewings (Neuroptera), grasshoppers (Orthoptera), moths (Lepidoptera), flies (Diptera), caddis flies (Trichoptera), small bees, wasps and ants (Hymenoptera), beetles (Coleoptera), spiders (Araneae), earthworms (Oligochaeta) and snails (Gastropoda); usually heavily supplemented, principally in non-breeding season, by seeds of spruce, pine, fir and Douglas fir (*Pseudotsuga*), juniper, cypress (*Chamaecyparis*), beech, birch, aspen (*Populus*), rose (*Rosa*) and buckthorn (*Rhamnus*), berries of hawthorn (*Crataegus*), rowan (*Sorbus*) and dogwood (*Cornus*), and sap of birch, aspen and maple (*Acer*). Nestling diet principally spiders, but also some pine seeds. Stores food, mostly conifer seeds, larval lepidopterans and spiders, throughout year in holes and crevices in bark of tree trunks, also in clumps of lichens on branches (rarely on ground), items wedged in place or covered with saliva or gossamer, insects usually partly decapitated or otherwise paralysed and often stored while still alive; caches insect larvae chiefly in autumn, as food supply for winter; stores not relocated by memory but apparently sited in areas where individual likely to be foraging; caches often exploited by several individuals in winter social group. Usually solitary or in pairs; where densities fairly high, occurs in non-breeding season in small groups of up to six (exceptionally, twelve or slightly more), usually comprising one or more mated pairs and several, probably unrelated juveniles; also joins mixed-species foraging flocks with other tits, especially *Poecile montanus*, and Eurasian Treecreepers (*Certhia familiaris*) and Goldcrests (*Regulus regulus*). In Scotland, where density lowest, usually solitary in non-breeding season but may join roving bands of tits or other small insectivores as they pass through its territory. Active, agile and restless, occasionally inquisitive. Forages mostly in upper and canopy levels of conifers during summer; at other times descends to lower levels to feed in lower branches of saplings, in undergrowth and on ground, where forages for fallen seeds or insects, and in N of range feeds on ground beneath well-established clumps of heather during winter snow periods; often follows squirrels (Sciuridae) feeding on cones, and collects spilled seeds. Occasionally visits birdtables in areas close to breeding sites. Searches foliage and lichen clumps; clings to branches, and extracts seeds from cones while hanging upside-down from slender twigs or occasionally while hovering; also extracts grubs from behind bark or in dead wood.

**Breeding.** Season Mar–Jun; one brood, in S occasionally two. Monogamous, with lifelong pair-bond; in Russian study, estimated c. 90% of pairs formed by first-time breeders and widowed adults, and most pairs formed from within winter social group. Territory maintained and defended throughout year. Display includes courtship-feeding of female by male. Nest built by female, a cup of moss, lichens, animal hair, wool, feathers and gossamer, placed mostly within 3 m (exceptionally 13 m) of ground in hole in dead or decaying tree trunk, branch or stump, occasionally in living tree, old hole of woodpecker (Picidae), disused crow (Corvidae) or raptor nest or squirrel drey, sometimes in hole in fence post or in ground; nest-hole excavated or enlarged by pair, principally by female; nestboxes also regularly used; territory size not well known, but home range (most of which is territory) 6–11 ha in most of Europe, although in Scotland (where population sparse) extent of territorial defence indicates that territory apparently poorly defined. Clutch 5–11 eggs, smallest clutches in N of range; incubation by female, period 13–18 days; chicks fed by both parents, nestling period 16–22 days; young dependent on adults for up to further 23–25 days. Breeding success variable, average number of young fledged per brood 4.7 in Finland to 5.9 in S Germany, success rate generally lower for natural holes (reason unknown); main nest predator Great Spotted Woodpecker (*Dendrocopos major*), and in study in Pskov area (NW Russia) predation of nest-sites by woodpeckers 39–60% and average success 3.27 young per pair. Breeds in first year. Maximum recorded longevity (from ringing data) 7 years 7 months; annual adult mortality in Russian study 73%.

**Movements.** Largely resident; also nomadic in winter. In N of range occasionally wanders up to 100 km from breeding areas in non-breeding season, including to Lapland, S Kola Peninsula and mouth of R Pechora, and also S to Ukraine and Moldova. Vagrants recorded in C Siberia, Kazakhstan, England (also Scotland away from breeding areas) and Morocco.

**Status and Conservation.** Not globally threatened. Common or fairly common in most of range; uncommon and local in Scotland, and rare in W & NE Hungary. Estimated European breeding population 3,600,000–4,800,000 pairs, most of which (more than 1,000,000 pairs) are in Spain and Belarus. Throughout entire range, but more predominantly in N, population levels fluctuate in response to periods of severe winter weather. Densities vary from 48 pairs/km<sup>2</sup> in NE France, and 40 pairs/km<sup>2</sup> in pine woods in NW Spain and cork oak in Portugal, to 17 pairs/km<sup>2</sup> in mature pines in C Scotland (but only 1 pair/km<sup>2</sup> in mixed-age plantations) and 2–3 pairs/km<sup>2</sup> in pine-spruce forests in N Finland. Range has expanded W in C & S France, Belgium and Netherlands and N in Denmark and parts of Finland following increase and spread of commercial conifer plantations. Conversely, overall decline of c. 50% in population in Finland between 1955 and 1985 owing to modernization of forestry practices, and in same period a decline by c. 20% in Sweden and Czech Republic balanced by increases in Spain, Italy and Hungary. At study site in the Erzgebirge of E Germany, local declines of up to 30% (largely through increased adult mortality and reduced productivity) due to atmospheric pollution of conifer forests. In Scotland, range contracted during 18th century, following destruction of native Caledonian pine forest; some recovery in numbers occurred in latter half of 20th century, and population now stable at c. 900 pairs; despite abundance of new commercial forestry plantations, however, there has been no movement away from traditional range.

**Bibliography.** Barnes (1975), Brown & Grice (2005), Cramp & Perrins (1993), Dementiev *et al.* (1954, 1970), Échécopar & Hie (1967), Flint *et al.* (1984), Gibb (1960), Gibbons *et al.* (1993), Gill *et al.* (2005), Glutz von Blotzheim & Bauer (1993), Gorman (1996), Hagemeijer & Blair (1997), Handrinos & Akriotis (1997), Harapp & Quinn (1996), Harrison (1982), Hartert (1905, 1921), Jouard (1929), Lohrl (1991), McCarthy (2006), Perrins (1979), Rogacheva (1992), Svensson *et al.* (1999), Vaurie (1959).

22. Grey-crested Tit

*Lophophanes dichrous*

**French:** Mésange des bouleaux      **German:** Grauhaubenmeise      **Spanish:** Herrerillo Crestigris  
**Other common names:** Brown Crested Tit

**Taxonomy.** *Parus dichrous* Blyth, 1845, Nepal.

Until recently present genus normally subsumed into a broad *Parus*, and many authors still prefer that treatment. Relationship with *L. cristatus* uncertain; further study needed. Both were previously considered, on grounds mainly of morphology, to have close affinity with *Baeolophus wollweberi*. Race *wellsi* intergrades with both nominate and *dichroides* in S China. E Himalayan populations perhaps separable from nominate as race *izzardii*, on basis of longer wing. Four subspecies recognized.

#### Subspecies and Distribution.

*L. d. kangrae* Whistler, 1932 - NW Himalayas (Jammu and Kashmir E to Kumaon).

*L. d. dichrous* (Blyth, 1845) - C & E Himalayas E to SW China (S Xizang).

*L. d. dichroides* Przevalski, 1876 - C China (E & S Qinghai, S Gansu and S Shaanxi S to N Sichuan).

*L. d. wellsi* (Stuart Baker, 1917) - S China (E Xizang E to N Sichuan and W & N Yunnan) and NE Myanmar.

**Descriptive notes.** 11.5–12.5 cm; 11.2–14 g. Medium-sized, plain grey tit with long erect crest and buffish underparts. Nominative race has pale buffish lower forehead, becoming grey on upper forehead and deeper grey on crown and crest; upperparts, including upperwing-coverts, mostly uniform plain grey, tinged buffish, except for dark grey upper edge of mantle; tail darker, brownish-grey, broadly fringed paler or buffish-grey; alula, primary coverts and flight-feathers blackish, finely fringed paler; lores, cheek and ear-coverts pale buff, finely tipped grey (mottled effect), rear and lower edges of ear-coverts greyer, fairly broad whit-

ish submoustachial stripe and buffish-white half-collar; chin and throat greyish-buff or greyish-brown; underparts orange-buff, sometimes tinged warmer brown, also whiter on belly and vent; in worn plumage, upperparts slightly darker grey and underparts paler buff; iris variably brownish-orange to crimson; bill dark grey to black; legs dark grey to bluish-grey. Sexes alike. Juvenile is similar to adult, but crest shorter, crest and upperparts slightly darker, rump tinged buffish, cheeks, ear-coverts and throat paler and less extensively buffish-brown. Racial variation slight: *kangrae* is as nominate, but upperparts slightly paler grey, face heavily flecked greyer, submoustachial paler and indistinct, neck side slightly paler, chin and throat greyish-buff (sometimes darker grey on lower throat) and contrasting with dull rufous or cinnamon-buff wash on rest of underparts; *wellsi*

has upperparts slightly darker grey than nominate, generally paler below, chin and throat to breast and belly dull pale buff (no contrast between throat and breast), variably rich cinnamon to pale cinnamon-buff on belly side, flanks and vent; *dichroides* is similar to last, but crown, crest and nape paler than dark grey upperparts, and underparts almost uniformly washed cinnamon-buff, paler on throat and breast and heavier on flanks. Voice. Fairly quiet. Calls include thin or high-pitched “zee” or “zai” and rapid but faltering “ti-ti-ti-ti” or “tirrit tizit tizit”, also softer “sip-sip-sip” or “sip-pi-pi” or “tsip-it, sit, tsit-tsit, scheip” or “tchuit psip cheeip-ptcheeip-scheip” together with more plaintive “pee-di” or “pi-diu”; alarm a rapid “chee chee”. Song mainly a series of “whee-whee-tz-tz-tz”, with various call notes and trills incorporated.

**Habitat.** Forests, in Himalayas including oak (*Quercus*) and rhododendron (*Rhododendron*) broadleaf forest, and mixed fir (*Abies*), hemlock (*Tsuga*), oak and rhododendron, pine (*Pinus*), spruce (*Picea*) and birch (*Betula*); in Myanmar in similar mixed fir forests but with bamboo and hydrangea. Breeds at 2400–3300 m in NW India, 2450–4000 m (possibly to 4270 m) in Nepal, 2440–3960 m in Sikkim, 2745–4240 m in Bhutan, to 2700 m in W Arunachal Pradesh, 2745–3200 m in NE Myanmar, and generally 2480–4000 m in SW China but at 2300–4570 m in Sichuan; also lower in non-breeding season, down to 2200 m in N India and at 2000–3600 m in Nepal and Bhutan, but many remain at higher levels, and regularly winters at 2440–3050 m in Sichuan.

**Food and Feeding.** Food apparently mostly invertebrates and larvae. Usually in pairs or small groups; occasionally pairs join mixed-species foraging flocks with other parids, particularly *Pariparus ater*, and leaf-warblers (*Phylloscopus*). Generally shy, fairly quiet and unobtrusive. Forages in middle to lower levels of forest trees, also in undergrowth and shrub layers; also on ground, especially in winter, when recorded collecting food items beneath dwarf rhododendrons and birch scrub.

**Breeding.** Season Apr to at least Jun. Nest a pad or small platform of moss, animal fur or hair and feathers, placed 3–7 m from ground in hole or cavity in tree trunk or old stump (may be excavated by nesting pair). Clutch 4–5 eggs; chicks fed by both parents. No other information.

**Movements.** Resident and short-distance altitudinal migrant. Some descend to lower levels (often within lower limits of breeding range) in non-breeding season, as in Nepal and Bhutan and elsewhere in Himalayas, but many remain at higher elevations unless forced by severe weather to move lower.

**Status and Conservation.** Not globally threatened. Uncommon in W Himalayas and S China, but fairly common in E Himalayas; locally common in N Myanmar. Occurs in several protected areas, including Foping Panda Reserve, in China.

**Bibliography.** Ali & Ripley (1983), Cheng Tsohsin (1987), Choudhury (2003), Étiénnecopar & Hôe (1983), Fleming *et al.* (1979), Gill *et al.* (2005), Grimmett *et al.* (1998), Harrap & Quinn (1996), Hartert (1905), Inskipp & Inskipp (1991), King *et al.* (1975), MacKinnon & Phillipps (2000), Mariens & Eck (1995), Meyer de Schauensee (1984), Rasmussen & Anderton (2005), Robson (2000), Singh (1999), Smythies (1986), Spierenburg (2005), Stuart Baker (1932), Vaurie (1959).

# Genus *BAEOLOPHUS* Cabanis, 1850

## 23. Bridled Titmouse

### *Baeolophus wollweberi*

French: Mésange arlequin German: Zügelmeise Spanish: Herrerillo Embridado

**Taxonomy.** *Lophophanes wollweberi* Bonaparte, 1850, Zacatecas, Mexico.

Until recently present genus normally subsumed into a broad *Parus*, and many authors still prefer that treatment; present species has also been placed in *Lophophanes* by some, but molecular-genetic data indicate a much closer relationship to other members of present genus. Nominate race and *phillipsi* intergrade in NW Mexico; *caliginosus* often merged with nominate. Four subspecies recognized.

#### Subspecies and Distribution.

- B. w. vandevenderi* (Rea, 1986) – SW USA (C Arizona, extreme SW New Mexico).
- B. w. phillipsi* (van Rossem, 1947) – SW USA (SE Arizona) and NW Mexico (E Sonora, Chihuahua, N Sinaloa, N Durango).
- B. w. wollweberi* (Bonaparte, 1850) – C & S Mexico (Sinaloa and Durango and C Nuevo León S to Michoacán and Puebla).
- B. w. caliginosus* (van Rossem, 1947) – SW Mexico (Guerrero, Oaxaca).

**Descriptive notes.** 11.5–13.5 cm; 8.8–11.7 g. Medium-sized, crested tit with black-and-white face pattern and black bib. Nominate race has upper forehead and crown grey, sides of forehead and crown to short pointed crest blackish, nape (including side of nape) also blackish or tinged olive-grey; lower forehead, lores and supercilium white or whitish, extending in a band down behind ear-coverts to side of neck, narrow blackish line from eye along upper and rear edges of ear-coverts; cheek and ear-coverts white (or washed buffish), becoming greyer at rear; upperparts and tail grey or olive-grey, outer tail feather narrowly edged

whitish; upperwing as upperparts, tinged greyish-brown on lesser wing-coverts, flight-feathers grey-brown, fringed olive-grey; chin and throat black, underparts whitish-grey with yellowish-buff tinge, greyer on lower flanks; in worn plumage, crown darker, upperparts greyer, wings slightly browner, sometimes dark feather bases visible on cheeks and ear-coverts, and underparts whiter; iris brown; bill black; legs dark bluish-grey. Sexes alike. Juvenile is similar to adult, but crest shorter and blackish-grey, nape browner, upperparts pale grey-brown, flight-feathers edged off-white, supercilium to neck side off-white, cheeks and ear-coverts buffish-white, chin and throat dark grey, breast pale grey. Racial variation slight, and usually best detectable when comparing birds in fresh plumage: *phillipsi* is slightly smaller and paler grey than nominate, less olive on rump and edges of tail feathers, underparts paler grey (less yellow), but some regional variation, individuals with brighter upperparts and yellower underparts in S Arizona; *vandevenderi* is as previous, but upperparts slightly darker grey and with olive wash, underparts also darker, breast and flanks grey and centre of belly whitish (lacking yellow wash); *caliginosus* is similar to nominate but generally poorly marked, slightly darker olive-toned both above and below. VOICE. Calls include frequently given “chick-a-dee-dee”, also metallic “psit”, sibilant “sik” or sharper “tsik”, high-pitched “tsit” or “chit”, latter either singly or in rapid staccato rattle as “chit-it-it-it-it” or “tsi-tsi-si si si serr-eh-eh”; also a short “churr”, which may be run into longer chattering “ch-r-r-r-r-r-r-r-r-r-r”; usually shows strong reaction to calls (including imitations) of Mountain Pygmy-owl (*Glaucidium gnoma*). Song a monotonous and rapidly delivered repetitive series of “pli” or “chi” notes, also an upwardly slurred “cheewee” or “weet-weet” whistle repeated up to eight times.

**Habitat.** Evergreen montane forests of oak (*Quercus*), pine (*Pinus*) and juniper (*Juniperus*), occasionally also American plane (*Platanus occidentalis*), often in areas of dense scrubby forest; in Arizona breeds also in lower-level willows (*Salix*), cottonwood (*Populus*) and mesquite (*Prosopis*), and in winter spreads more widely into riparian woodland and occasionally in similar habitat in suburban and city parks. In USA occurs at c. 1500–2100 m, wandering to c. 2600 m; in Mexico mostly at 1000–3000 m, dispersing to higher levels (to at least 3200 m in C Mexico), and recorded rarely down to 560 m.

**Food and Feeding.** Diet not well known, but presumed to include small invertebrates and larvae. Food-caching recorded in captivity, but not documented for wild-living individuals. Usually in pairs, and after breeding forms family parties of up to ten individuals; later in autumn, parties may join together to form larger social groups; also found in mixed-species flocks. Tame, approachable and often confiding. Forages mostly in middle and lower levels of forest trees, spending most time in the interior around the bark and among branches, including slender twigs; also hangs from slender branches to examine underside of leaves. Rarely on ground.

**Breeding.** Poorly known. Season at least Apr to early Jun; probably single-brooded. Territorial during breeding. Nest an untidy mat or platform of leaves, lichens, plant down and fibres, and animal fur or human hair, placed up to 8.5 m above ground in natural hole or cavity in tree trunk or stump (oak most frequently used), or often uses old hole of woodpecker (Picidae) or nestbox. Clutch 5–7 eggs. No further information.

**Movements.** Resident, with some short-distance descent to lower levels in non-breeding season. During Sept to early Apr may be found at somewhat lower elevations, principally along river valleys, S & W of breeding range; few records beyond this immediate area, but wanders in USA occasionally to S New Mexico and in Mexico to NC Sonora. Vagrant in Texas.

**Status and Conservation.** Not globally threatened. Common or fairly common; locally abundant in Arizona. Some expansion of breeding range in Arizona; this countered by some withdrawal in non-breeding range owing to destruction of riparian woodland along R Gila and lower R Salt.

**Bibliography.** Anon. (1983b, 1998a), Bent (1946), Christman (2002), Farrand (1985), Gill *et al.* (2005), Harrap & Quinn (1996), Howell & Webb (1995), Nosedal & Ficken (1998a, 1998b), Phillips (1986), Phillips *et al.* (1964), Pyle (1997), van Rossem (1947).

## 24. Oak Titmouse

### *Baeolophus inornatus*

French: Mésange unicolore German: Schlichtmeise Spanish: Herrerillo Unicolor  
Other common names: Plain Titmouse (when treated as conspecific with *B. ridgwayi*)

**Taxonomy.** *Parus inornatus* Gambel, 1845, near Monterey, California, USA.

Until recently present genus normally subsumed into a broad *Parus*, and many authors still prefer that treatment. Forms a superspecies with *B. ridgwayi*, *B. bicolor* and *B. atricristatus*; until recently treated as conspecific with *B. ridgwayi*, but differs in morphology and voice. Nominate race and *affabilis* intergrade in SW California (USA). Race *mohavensis* sometimes merged with latter. Other proposed races, all in USA, include *sequestratus* (SW Oregon and NW California) and *kernensis* (drainage basin of R Kern and adjacent E slopes of Sierra Nevada, in California), both synonymized with nominate, and *transpositus* (SW California W of the deserts), merged with *affabilis*. Four subspecies currently recognized.

#### Subspecies and Distribution.

- B. i. inornatus* (Gambel, 1845) – SW USA (SW Oregon S to SW & SC California).
- B. i. affabilis* Grinnell & Swarth, 1926 – SW California and extreme NW Mexico (N Baja California).
- B. i. mohavensis* (A. H. Miller, 1946) – SE California (Little San Bernardino Mts).
- B. i. cineraceus* (Ridgway, 1883) – W Mexico (S Baja California).

**Descriptive notes.** 15–16 cm; 12.6–19.2 g. Large, grey tit with short crest. Nominate race has crown, crest and upperparts, including upperwing-coverts, grey-brown, back slightly warmer brown, rump slightly paler or buffish-brown, centres of greater coverts dark grey; tail dark grey-brown, fringed paler or greyer; flight-feathers dark grey, tertials, secondaries and inner primaries with fine grey-brown edges; forehead and lores to cheek and ear-coverts plain grey or mottled finely darker, neck side off-white, chin, throat and centre of upper breast pale grey, rest of underparts pale buffish-grey, becoming more buffish or light

brown on lower flanks and undertail-coverts; iris dark brown; bill dull dark grey; legs dull bluish-grey. Differs from *B. ridgwayi* in slightly smaller size, smaller bill, brown tinge in upperparts, and voice. Sexes alike. Juvenile is as adult, but may have paler tips on greater coverts, and tail feathers more pointed. Races vary little: *affabilis* resembles nominate, but bill larger, upperparts slightly dusky brown (less grey), underparts duller, flanks washed grey-brown, in SW California plumage slightly browner (“*transpositus*”); *mohavensis* is like previous but slightly paler or greyer, and flanks washed pale grey; *cineraceus* is as nominate, but on average slightly smaller (especially bill and tail), and has upperparts greyer and underparts paler. VOICE. Calls include soft “sip” or “sisip”, “sit-sit” or “si-si-pit” and “si si si chrr” and variations, including “tsitzi-tzer, tsitsi-tzer, tsitsitsi-tzer-zet”, often as a more scolding “see-jert-jert” or “tzer-zet-zet-zet”, and a thin high-pitched “see-see-see”. Song, mostly Feb–May in California, a repeated series of whistled “pli” or “tui” notes, often in combinations as e.g. “pee-chee pee-chee pee-chee” or a more prolonged “pli-pli, chuwi-chuwi-chuwi-chuwi, tsit-tsit-chiu, tsit-tsit-chiu, tsit-tsit-chiu”.

**Habitat.** Mostly lowland dry evergreen woodlands, mainly of oak (*Quercus*) but may also include pine (*Pinus*), juniper (*Juniperus*) or California laurel (*Umbellularia californica*); also in chaparral, riparian alders (*Alnus*) and fairly well-wooded suburban areas (in all cases, usually in vicinity of oaks). Occurs to c. 1100 m in N & C California, at 1340–2285 m (has occurred to 2440 m) in W California, and to c. 2050 m in S; at 500–2400 m in Mexico (Baja California).

**Food and Feeding.** Food includes small invertebrates and larvae; also acorns, leaf buds, catkins, and some fruit, principally berries. Usually solitary, in pairs and (for c. 1 month after fledging) in family groups, and may also join mixed-species flocks as these pass through pair’s territory. Fairly inconspicuous, and heard more often than seen. Forages in middle to upper level of forest trees, gleaning from among foliage and bark; able to strip away short sections of bark to reach insects. Occasionally, and mostly in non-breeding season, forages on ground. Also visits birdtables.

**Breeding.** Season late Mar to mid-Jul; one brood. Pair-bond maintained for life. Territory defended throughout year, particularly in spring and also after breeding (against incursion from wandering juveniles). Nest built by female, mostly of moss, plant fibres, bark strips, animal fur and feathers, placed 1–3 m above ground in hole or cavity in tree trunk, often in old hole of woodpecker (Picidae), and most frequently in oak, juniper or Joshua tree (*Yucca*); may adapt or excavate nest-site in rotten wood; nestbox or other artificial site frequently used; site often reused in subsequent years. Clutch 6–9 eggs, and female may roost on nest for up to a month before laying; incubation by female, fed by male during incubation, period up to 16 days; chicks fed by both sexes, most food brought by male, nestling period 16–21 days; young fed by parents for up to 28 days after leaving nest; juveniles often defend own territories from Aug onwards (exceptionally from Jun), but sites often unsuitable and usually abandoned before following spring, while some juveniles either wander or occupy marginal habitats until finding a suitable territory or an unmated territory-owner.

**Movements.** Mainly resident; some, possibly juveniles, make short-distance movements to lower levels at periphery of breeding range.

**Status and Conservation.** Not globally threatened. Considered to be common or fairly common throughout range.

**Bibliography.** Anon. (1983b, 1998a), Bent (1946), Cicero (1996, 2000, 2004), Dixon (1949), Farrand (1985), Gaines (1992), Gill *et al.* (2005), Harrap & Quinn (1996), Howell & Webb (1995), McCarthy (2006), Pyle (1997), Sibley (2000).

## 25. Juniper Titmouse

### *Baeolophus ridgwayi*

French: Mésange des genévriers German: Wacholdermeise Spanish: Herrerillo de Ridgway  
Other common names: Ridgway’s Titmouse; Plain Titmouse (when treated as conspecific with *B. inornatus*)

On following pages: 26. Tufted Titmouse (*Baeolophus bicolor*); 27. Black-crested Titmouse (*Baeolophus atricristatus*); 28. White-shouldered Black Tit (*Parus guineensis*); 29. White-winged Black Tit (*Parus leucomelas*); 30. Southern Black Tit (*Parus niger*); 31. Carp’s Black Tit (*Parus carpi*); 32. White-bellied Tit (*Parus albigentis*); 33. White-backed Black Tit (*Parus leuconotus*); 34. Dusky Tit (*Parus funereus*); 35. Rufous-bellied Tit (*Parus rufiventris*); 36. Cinnamon-breasted Tit (*Parus pallidiventris*); 37. Red-throated Tit (*Parus fringillinus*); 38. Stripe-breasted Tit (*Parus fasciiventris*); 39. Somali Tit (*Parus thruppi*); 40. Miombo Tit (*Parus griseiventris*); 41. Ashy Tit (*Parus cinerascens*); 42. Grey Tit (*Parus afer*).

**Taxonomy.** *Parus inornatus ridgwayi* Richmond, 1902, Iron City, Utah, USA.

Until recently present genus normally subsumed into a broad *Parus*, and many authors still prefer that treatment. Forms a superspecies with *B. inornatus*, *B. bicolor* and *B. atricristatus*; until recently treated as conspecific with *B. inornatus*, but differs in morphology and voice. Race *zaleptus* poorly differentiated, and species sometimes treated as monotypic. Supposedly darker birds in S of range (S from NC Arizona and SW New Mexico) proposed as race *plumbescens*, but appear to fall within range of variation of nominate. Two subspecies recognized.

**Subspecies and Distribution.**

*B. r. zaleptus* Oberholser, 1932 – W USA (SE Oregon, E California, W Nevada).

*B. r. ridgwayi* (Richmond, 1902) – WC USA (S Idaho E to Colorado and extreme W Oklahoma, S to SE Arizona, New Mexico and extreme W Texas) and extreme N Mexico (NE Sonora).

**Descriptive notes.** 15–16 cm; 15.2–23.1 g. Large tit with short crest, grey upperparts and whitish underparts. Nominative race has crown, crest and upperparts, including upperwing-coverts, grey, centres of greater coverts dark grey; tail dark grey-brown, fringed paler or greyer; flight-feathers dark grey, tertials, secondaries and inner primaries with fine pale grey edges; forehead and lores to cheek and ear-coverts plain grey or whitish-grey, mottled finely darker, side of neck dull grey, tinged brownish; chin, throat and centre of upper breast whitish-grey, rest of underparts pale grey, becoming grey-buff on lower flanks and

undertail-coverts; iris dark brown; bill dull dark grey; legs dull bluish-grey. Differs from *B. inornatus* in slightly larger size, larger bill, grey (not brown) upperparts, and voice. Sexes alike. Juvenile is as adult, but may have paler tips on greater coverts and more pointed tail feathers. Race *zaleptus* is very similar to nominate, but in fresh plumage a little paler grey, tinged brown on nape, mantle and back, and whitish-grey below, sometimes slight buff tinge on flanks. Voice. Calls include soft “tup”, thin “sit” and scolding “churr-rrrrrrrr”. Song types include fast, rattling “jijiji jijiji jijiji...” on even pitch, sometimes interspersed with “chi-chi-chipu-chi-chi-chipu” whistles, also a monotonous, unmusical and rapid “pli-li-li-li-li-li” or “chwi-wi-wi-wi-wi-wi-wi”.

**Habitat.** Breeds in pinyon-juniper (*Pinus-Juniperus*) woodland, occasionally with oak (*Quercus*) intermixed, and in scrub oak woodland; in non-breeding season found in ponderosa pine (*Pinus ponderosa*) and more riparian areas, including alder (*Alnus*) and willow (*Salix*) thickets, and in dry sagebrush (*Artemisia*) scrub. To at least 2135 m in Arizona and at 1440–2440 m in New Mexico.

**Food and Feeding.** Food includes small invertebrates and larvae; also acorns, leaf buds and some fruit, principally berries. Usually solitary or in pairs, also in family groups, especially in non-breeding season; may join mixed-species flocks as these pass through breeding territory. Fairly inconspicuous, heard more often than seen. Forages in middle and upper levels of trees, gleaning from foliage and bark; occasionally on ground, mostly in non-breeding season. Behaviour and foraging actions very similar to those of *B. inornatus*, but in non-breeding season seen more often in small single-species flocks than in latter species.

**Breeding.** Not well documented. Season mid-Apr to late Jul. Nest made mostly of hair, grass, bark, moss and rootlets; placed 0.3–3.6 m above ground in hole or cavity in tree trunk, often in old hole of woodpecker (Picidae), and most frequently in juniper, but also in piñon and oak; nestbox or other artificial site frequently used. Clutch 6–7 eggs (3–9); incubation by female; incubation and nestling periods reported to be similar to those of *B. inornatus*, but no precise data available. No further information.

**Movements.** Mainly resident. Some, probably juveniles, make short-distance movements in Sept–Mar to lower levels at periphery of breeding range, including to base of Grand Canyon (Arizona); in W Texas more numerous in non-breeding season in Guadalupe Mts, and has occurred E to Davis Mts and El Paso.

**Status and Conservation.** Not globally threatened. Generally rather local or uncommon; rare in N Mexico (Sonora).

**Bibliography.** Anon. (1983b, 1998a), Bent (1946), Cicero (1996, 2000, 2004), Cooper & Gessaman (2004, 2005), Harrop & Quinn (1996), McCarthy (2006), Phillips (1959), Pyle (1997), Sibley (2000).

## 26. Tufted Titmouse

### *Baeolophus bicolor*

**French:** Mésange bicolore

**German:** Indianermeise

**Spanish:** Herrerillo Bicolor

**Other common names:** Eastern Tufted Titmouse

**Taxonomy.** *Parus bicolor* Linnaeus, 1766, South Carolina, USA.

Until recently present genus normally subsumed into a broad *Parus*, and many authors still prefer that treatment. Forms a superspecies with *B. inornatus*, *B. ridgwayi* and *B. atricristatus*. Was until recently treated as conspecific with last of these, and the two hybridize in a narrow zone in C Texas, but they generally differ somewhat in ecology; further study required. Monotypic.

**Distribution.** Extreme SE Canada (S Ontario) and E USA (SE Minnesota E to S Maine, S to C & E Texas and S Florida).

**Descriptive notes.** 11.5–14 cm; 17.5–26.1 g. Large, short-crested and fairly long-tailed grey tit. Has forehead to upper lores black, occasionally tinged rust-brown, crown and short pointed crest mid-grey with darker shaft streaks; upperparts, including upperwing-coverts, mid-grey, scapulars and back to uppertail-coverts tinged brownish-olive, centres of greater coverts dark grey; tail dark grey-brown, feathers fringed paler or greyer; flight-feathers mid-grey, tertials, secondaries and inner primaries with fine pale grey edges; lores whitish, tinged warm buff, cheek, ear-coverts and neck side plain whitish-grey; chin, throat

and upper breast white, washed pale grey, flanks rich rufous-buff, rest of underparts white with faint buffish wash; iris dark brown; bill black or dull dark grey; legs dull lead-grey. Differs from *B. atricristatus* mainly in black forehead and plain grey crest. Sexes alike. Juvenile is as adult, but has less black on forehead, upperparts tinged browner, breast greyer, and may have buffish tips on greater coverts and more pointed tail feathers. Voice. Fairly noisy; calls include loud, whistled “see-toit” and “seeja-wer” or “peta peta peta”, and variants such as harsher “day-day-day”, or

lower-pitched “tsee-day-day-day” similar to that of *Poecile carolinensis*; also an excited and high-pitched “tsi-tsi-tsi-sii-sii-zhree zhree zhree” and “tsit”, “sit-sit-sit” or “tset” contact notes, and in alarm a high-pitched “see-see-see”. Song, throughout year but mainly Feb–Sept, a whistled but slightly slurred “pli-piu” or longer and more drawn-out and descending “weedle petoo peeđu”, repeated up to ten times, also slower and more rolling “peeta-peeta-peeta-peeta” or “pli-pli-pli-pli-pli”; both sexes sing, but female much less than male and apparently only during summer months.

**Habitat.** Lowland, mature deciduous and mixed woods, including white oak (*Quercus alba*), hickory (*Carya*) and sweet gums (*Eucalyptus*), favouring riverine valleys, streams and wooded swamps; in non-breeding season, also edges of cultivation and well-wooded farmland, and suburban areas, orchards, parks, hedgerows and scrub; in E Texas more regularly in higher-level oak woodland, and around the Gulf coast and Florida in conifer forest and cypress swamps. Lowlands, to 1500 m in Tennessee and occasionally to 1200 m in Kentucky.

**Food and Feeding.** Diet chiefly small invertebrates and larvae, principally weevils and other beetles (Coleoptera), bugs (Hemiptera), ants, bees, wasps and sawflies (Hymenoptera), flies (Diptera), snails and other small molluscs (Gastropoda), spiders (Araneae), also orthopteran eggs; also seeds and nuts, mostly acorns during non-breeding season. In studies, c. 38% of annual food intake comprised caterpillars. Stores large quantities of food within territory during summer and autumn, mostly in deep crevices in bark, along branches or in ground. Usually solitary or in pairs; after breeding season occurs in small family groups, and in mixed-species foraging flocks when these present within territory. Active and generally fairly vocal, partners and family-members maintaining frequent contact. Forages at all levels in trees (often in canopy in spring and winter), in undergrowth and on ground, where it searches among fallen leaves. Gleans food from among foliage, including while hanging from slender branches (although less often at end of branch), and examines bark crevices; occasionally hovers. Commonly visits feeders and birdtables, where dominant over all other bird species with the exception of Blue Jay (*Cyanocitta cristata*).

**Breeding.** Season late Mar to mid-Jun; occasionally two broods. Monogamous, pairs for life; single helpers noted as assisting with feeding of young at some nests. Territory defended pugnaciously throughout breeding season by resident pair, sometimes with one or two juveniles from previous season (may be defended also in non-breeding season, or small flocks of up to eight unrelated individuals may also be present within territory); sometimes two pairs (or two distinct breeding territories) within a larger territorial area, usually a dominant pair, and a second pair formed between members of previous winter's flock, and in such instances dominant pair usually establishes breeding territory up to a month ahead of second pair. Courtship display includes mutual wing-quivering, and feeding of female by male. Nest built by female, a cup mostly of leaves, moss, strips of bark, grass and animal hair, also rags, string and shed snakeskin incorporated, placed 6–20 m above ground in natural hole or cavity in living or dead tree, often old hole of woodpecker (Picidae), or hole in rotten tree stump or fence post, or hollow metal pole or nestbox used; same nest-site may be used for several years in succession; size of territory variable, 3.2–5 ha. Clutch 5–7 eggs; incubation by female, fed on nest by male, period 12–14 days; chicks fed by both parents, nestling period 15–18 days; juveniles continue to be fed by adults for up to 8 weeks; if two broods, young from first brood help to care for and feed second brood. Maximum recorded longevity 13 years 3 months.

**Movements.** Resident; some short-distance movements. Evidence from ringing shows that very few move more than 30 km from site where ringed. Some post-breeding dispersal and wandering in non-breeding season, from Sept/Oct to about Feb/Mar; irregular visitor to N Minnesota, N Wisconsin and W Texas, and in Canada rare visitor in S Quebec (but at least 50 recorded in irruption in winter 1990/91) and vagrant in New Brunswick.

**Status and Conservation.** Not globally threatened. Generally common to locally common or locally scarce; rare to scarce in small Canadian part of range (S Ontario). Range expanded slowly N in 20th century; first recorded in Iowa and Wisconsin in early 1900s, and in Canada first record in May 1914 and first confirmed breeding in 1955 (possibly bred earlier, in 1932 and 1936), but subsequent increase in Canada very slow. Since 1946 has colonized New England, where now common in S, and from 1954 spread into N Pennsylvania and New York.

**Bibliography.** Anon. (1983b, 1998a), Avise & Zink (1988), Bent (1946), Braun *et al.* (1984), Dixon (1955, 1978), Farrand (1985), Gill & Slikas (1992), Gill, Funk & Silverin (1989), Gill, Slikas & Sheldon (2005), Godfrey (1986), Grubb & Pravosudov (1994), Harrop & Quinn (1996), McCarthy (2006), Pielou (1957), Pravosudova *et al.* (2001), Pyle (1997), Sibley (2000).

## 27. Black-crested Titmouse

### *Baeolophus atricristatus*

**French:** Mésange à plumet noir

**Spanish:** Herrerillo Crestinegro

**German:** Schwarzhäubchenmeise

**Taxonomy.** *Parus atricristatus* Cassin, 1850, Rio Grande, Texas, USA.

Until recently present genus normally subsumed into a broad *Parus*, and many authors still prefer that treatment. Forms a superspecies with *B. inornatus*, *B. ridgwayi* and *B. bicolor*. Was until recently treated as conspecific with last of these, and the two hybridize in a narrow zone in C Texas, but they generally differ somewhat in ecology; further study required. Races intergrade widely in overlap zones; proposed race *dysleptus* in S USA (W Texas) and adjacent N Mexico (S to Sierra del Carmen, in Coahuila) synonymized with *paloduro*. Birds of race *sennetti* have been referred to using the older names *castaneifrons* and *texasensis*, but both of these older names appear to be based on hybrids. Three subspecies recognized.

**Subspecies and Distribution.**

*B. a. paloduro* Stevenson, 1940 – S USA (N Texas, SW Oklahoma), also SW Texas (Trans-Pecos) S to N Mexico (extreme E Chihuahua, NW Coahuila).

*B. a. sennetti* Ridgway, 1904 – C & S Texas.

*B. a. atricristatus* (Cassin, 1850) – S Texas (Rio Grande Valley) and NE Mexico.

**Descriptive notes.** 14.5–15 cm; 15.5–20.9 g. Large, fairly long-tailed tit with black pointed crest and grey upperparts. Male nominate race has forehead whitish or pale buffish (sometimes a narrow dark line on centre), crown and crest black; upperparts, including upperwing-coverts, light grey to medium grey and tinged light olive, rump tinged olive-brown, centres of wing-coverts dark brownish-grey; tail dark brownish-grey, all outer feathers broadly fringed olive-grey; flight-feathers brownish-grey, all except outer primaries with fine pale grey edges; lores and area around eye whitish, cheek, ear-coverts and neck side plain whitish-grey; underparts mostly whitish, upper breast washed pale grey, flanks rich orange-buff or cinnamon, undertail-coverts washed buffish; in worn plumage, upperparts slightly paler grey but wings and tail browner and fringes abraded or paler, underparts duller, flanks paler; iris dark brown; bill black; legs dull bluish-grey. Distinguished from *B. bicolor* mainly by white forehead and black crest. Female is very like male, but crown and crest duller or less black, and crest shorter on average. Juvenile differs from adult in having forehead greyish-white, crown to (shorter) crest greyer, upperparts tinged browner, underparts washed dull

peew peew peew peew" or "pete-chee-chee-chee"; alarm a thin "see-see-see" or "sit-sit-sit"; calls similar to those of *B. bicolor* but louder and generally more nasal. Song a repeated, mellow, ringing "chew chew chew" whistle or variations, including "chee-u chee-u chee-u" or more slurred "p-lu p-lu p-lu" or "peter, peter, peter..." with second note higher; individual male may have up to twelve different song types.

**Habitat.** Mainly lowland dry forest, particularly mesquite (*Prosopis pubescens*) and scrub, including riparian woodland, e.g. cottonwoods (*Populus*), also juniper-oak (*Juniperus-Quercus*) woodland, possibly also mesquite and thorn-scrub; in Mexico, occurs on edges of evergreen forest in W Tamaulipas and in pine-oak/pinyon-oak (*Pinus-Quercus*) woodlands and forest in drier interior. In USA, occurs at 750–1065 m in S Oklahoma and W Texas, and 305–2135 m in Trans-Pecos and 1525–1675 m in Davis Mts, but generally below 750 m in S & SW Texas (down to c. 300 m in non-breeding season) and on coastal plain of E Mexico; in Mexico occurs to 1525 m in Hidalgo, to 1675 m in San Luis Potosí and at 1460–2285 m in NE Coahuila, and down to 150 m in Veracruz.

**Food and Feeding.** Diet chiefly small invertebrates and larvae, principally insects and spiders (Araneae); also some fruit, mainly berries, and during non-breeding season nuts, mostly pecan nuts (*Carya illinoensis*) and acorns. Usually solitary or in pairs in breeding season; forms small family parties of up to eight individuals in autumn and winter. Actively forages at all levels in trees (often in canopy in winter), in undergrowth and on ground; gleans food from among branches and foliage.

**Breeding.** Season late Feb to early Jun. Nest, usually built entirely by female, mostly of moss, grass, lichens, leaves, bark strips, animal hair and feathers, placed up to 7 m above ground in hole or cavity in (usually living) tree or old stump or in post (including telephone pole), frequently in old hole of woodpecker (Picidae) or nestbox; may reuse site in subsequent years. Clutch 6–7 eggs; incubation by female. No other information.

**Movements.** Mainly resident; occasional short-distance movements both to higher and to lower elevations in non-breeding season.

**Status and Conservation.** Not globally threatened. Generally common; uncommon in S parts of range in Mexico.

**Bibliography.** Anon. (1983b, 1998a), Avise & Zink (1988), Bent (1946), Braun *et al.* (1984), Dixon (1955, 1978), Gill & Slikas (1992), Gill *et al.* (1989), Grubb & Pravosudov (1994), Harrap & Quinn (1996), Howell & Webb (1995), McCarthy (2006), Pyle (1997), Sibley (2000).

## Genus *PARUS* Linnaeus, 1758

### 28. White-shouldered Black Tit

#### *Parus guineensis*

**French:** Mésange galonnée **German:** Guineameise **Spanish:** Carbonero Guineano  
**Other common names:** White-shouldered Tit

**Taxonomy.** *Parus leucomelas guineensis* Shelley, 1900, Volta River, Ghana.

Forms a superspecies with *P. leucomelas*, *P. niger*, *P. carpi* and *P. albiventris*, possibly also including *P. leuconotus*. Often considered conspecific with *P. leucomelas*, and the two occur in mixed flocks in Uganda, but they differ in eye colour, and no evidence of intergrades; further research required. Monotypic.

**Distribution.** S Senegal and S Mauritania E to S Sudan and N Eritrea, S to C Ivory Coast, SE Cameroon, N DR Congo, Uganda and extreme W Kenya.

**Descriptive notes.** 14 cm; 12.9–21 g. Large, dumpy, glossy black tit with short bill, pale eye, and large white patch on wing-coverts. Male has entire body and tail black (in fresh plumage, slight bluish gloss on upperparts to uppertail-coverts, and on neck side to breast), sometimes a short and untidy crest; tail slightly more sooty black, feathers glossed bluish-black on fringes, sometimes very narrow whitish fringe or tip on outermost two; lesser upperwing-coverts black, tipped white, median and greater coverts contrastingly white (greater with concealed dark shaft streaks) except for blackish outermost greater coverts; alula and primary coverts black, finely fringed or tipped white, flight-feathers blackish-brown, fringes of upper tertials glossy bluish, white on lowest tertial, secondaries broadly fringed white (forming, with that on wing-coverts, a broad white panel on closed wing), primaries narrowly fringed white or whitish; axillaries and underwing-coverts white; in worn plumage duller (less glossy) overall, and white in wing duller and abraded, with darker centres visible; iris mostly white to yellowish-white, sometimes pale buffish-brown; bill black; legs dark brown to bluish-grey or black. Distinguished from *P. leucomelas* by slight differences in glossy tinge and by pale eyes. Female differs from male only in having slightly smaller white patch in wing. Juvenile is as adult, but upperparts brownish-black, wings and tail sooty black, white on wing-coverts replaced by yellowish-white and often broader dark brown centres on outers (outermost greater coverts as adult), lowest tertial and edges of secondaries broadly yellowish-white and primary edges narrowly so, iris dull grey-

green to brown, bill may have some yellowish-white at base. **Voice.** Vocal; most frequent call a loud and rather harsh or rasping "churr" often introduced by 1–2 softer "chip" notes, also a nasal "dzwee, dzwee, dzwiu" or "ziu, dziu, dziu" repeated at intervals or when agitated or alarmed; other notes include thin "sisisi-pee" and harsh, grating "chut-chut"; calls very similar to those of *P. leucomelas*. Song a ringing series of whistles, "sree, tip-tu-wip, tu-wip, tu-wip, yu-wip" or variations, including "huwee-tee-huwee-tee-huweeh", "swip-pedu-wip, ped-du-wip..." and "way-teetwer-teetwer", "tee-tooyoo, tee-tooyoo, tee-tooyoo".

**Habitat.** Mature acacia (*Acacia*) savanna and open woodlands, grassland and thorn-scrub, including open areas of savanna within rainforest zone, edges of cultivation (but generally avoids agricultural areas) and in S Uganda more heavily wooded areas; in Eritrea occurs in highland juniper (*Juniperus*) woods and riparian thickets and gallery forest along rivers and streams. Lowland plains and hills, to 1220 m in Cameroon, to 1650 m in Eritrea, and above 1000 m in W Kenya.

**Food and Feeding.** Food includes small invertebrates and larvae, seeds and some fruit. Usually in pairs or in small groups (probably family parties) of up to eight individuals; also one of the main species in mixed-species foraging flocks in parts of W Africa. Active, and always on the move; generally shy. Forages in interior of middle level of trees, preferring to search trunk and branches rather than in foliage; may occasionally pursue and catch insects in flight.

**Breeding.** Poorly known. Season Jan–Jun/Jul. Nest placed up to 1 m from ground in hole in tree. No other information.

**Movements.** Mainly resident; scarce rainy-season visitor to S Mauritania.

**Status and Conservation.** Not assessed. Common or fairly common except along N & W boundaries of range. Rare (no recent records) on upper R Gambia but scarce or local on lower river; also scarce or uncommon in Mali and extreme SW Niger; common throughout most of Ghana but absent from coastal thickets. In Burkina Faso known only from Arli-Pendjari National Parks, where fairly common. Scarce in NE Central African Republic, NE Uganda and E Sudan, but locally common in N Uganda; rare in Eritrea and W Kenya.

**Bibliography.** Barlow & Wacher (2005), Borrow & Deme (2001), Britton (1980), Dowsett & Dowsett-Lemaire (1993), Elgood *et al.* (1994), Fry *et al.* (2000), Harrap & Quinn (1996), Lewis & Pomeroy (1989), Mackworth-Praed & Grant (1973), McCarthy (2006), Short *et al.* (1990), Sinclair & Ryan (2003), Stevenson & Fanshawe (2002), Zimmerman *et al.* (1996), Zinner (2001).

### 29. White-winged Black Tit

#### *Parus leucomelas*

**French:** Mésange à épaulettes **German:** Rüppellmeise **Spanish:** Carbonero Aliblanco  
**Other common names:** (Common) Black Tit, White-winged Tit

**Taxonomy.** *Parus leucomelas* Rüppell, 1840, Halei Province, Temben, Ethiopia.

Forms a superspecies with *P. guineensis*, *P. niger*, *P. carpi* and *P. albiventris*, possibly also including *P. leuconotus*. Often treated as conspecific with *P. guineensis*, and the two occur in mixed flocks in Uganda, but they differ in eye colour, and no evidence of intergrades; further research required. Possibly closer to *P. niger*, and sometimes considered conspecific with it, but the two appear not to interbreed in area of range overlap in Malawi and Zambia. Two subspecies recognized.

**Subspecies and Distribution.**

*P. l. leucomelas* Rüppell, 1840 – C & SE Ethiopia.

*P. l. insignis* Cabanis, 1880 – S Gabon and S PR Congo E to E DR Congo, SW Uganda, W Rwanda, N Burundi and NW & C Tanzania, S to Angola, Zambia and Malawi.

**Descriptive notes.** 15–16 cm; 21–24 g. Large, glossy black tit with dark eyes and large white patch on wing-coverts. Male nominate race has entire body and tail black (in fresh plumage, crown to uppertail-coverts glossed bluish or bluish-purple, slight gloss on side of neck to belly, less visible on flanks and undertail-coverts), sometimes a short and ragged crest on hindcrown; fringes of all tail feathers glossed bluish-black, faint narrow pale edge on outermost; lesser upperwing-coverts black, median and greater coverts contrastingly white (both have concealed black bases) except for blackish outermost greater coverts; alula and primary coverts black, finely fringed or tipped white, flight-feathers blackish-brown, fringes of upper tertials glossy bluish, white on lowest tertial, secondaries broadly fringed white (forming broad white panel on closed wing), primaries narrowly fringed white or whitish; axillaries black, underwing-coverts black with white tips; in worn plumage duller (less glossy) overall, white in wing duller and abraded, and darker centres of greater coverts visible; iris dark grey or brown; bill black; legs dark brown to bluish-grey or black. Distinguished from *P. guineensis* by slight differences in glossy tinge and by dark eyes; from *P. niger* by blacker general plumage, especially on belly to undertail-coverts, and more solidly white greater coverts. Female is very like male but duller, less glossy, and with underparts sooty black. Juvenile is as adult, but upperparts blackish-brown, wings and tail sooty black, white on wing-coverts replaced by yellowish-white, broader dark brown centres of greater coverts visible (outermost greater coverts as adult), lowest tertial and edges of inner secondaries broadly white, fringes of outer secondaries and narrower fringes of primaries tinged yellowish-buff. Race *insignis* differs from nominate in having gloss on body plumage bluish to bottle-green, tail feathers (except central pair) often with very narrow whitish fringe or tip, underwing-coverts more extensively white. **Voice.** Calls include shrill and abrupt "chut" or "chit", usually as introduction to buzzing "chit-zzzzz-r" or "chut-drrrrrr-du" and lower-pitched "chik-zworrtrr, chik-zworrtrr", also more musical "tszee-tuuu, tszee-tuuu" and "pss-tyoo-yoo, pss-tyoo-yoo". Song a "ter-si, du, l-l-l-l-l-tuwi" or "wheee-to-trrrr-tooe" whistle, rather similar to that of a *Turdus* thrush.

**Habitat.** In Ethiopia (nominate race), found in dry podocarpus forests of juniper (*Juniperus*) and olive (*Olea*) in highlands and in lower-lying subtropical riverine forest and acacia (*Acacia*) thornbush savanna; to c. 2750 m. In C Africa principally in grassland savanna with acacia thornbush, occasionally in miombo or secondary brachystegia (*Brachystegia*) woodlands, and in Malawi also in riparian scrub and montane grassland with scattered trees, also edges and clearings in light miombo woodland and edges of acacia savanna; in coastal Angola occurs in mistbelt woodland below the escarpment. Generally above 915 m, to at least 1860 m in DR Congo, to 2040 m in Zambia and S Malawi; to 2000 m in E Africa but in places may occur at lower levels, down to 760 m near L Tanganyika.

**Food and Feeding.** Food includes small invertebrates and larvae, also seeds and some fruit, in particular custard-apple fruit (*Annona*). Usually in pairs or in small groups (probably family parties) of up to six individuals; also in fast-moving mixed-species foraging flocks containing small

warblers (Sylviidae) and Spotted Creepers (*Salpornis spilonota*). Actively and diligently forages in interior of tall trees, preferring to search trunk rather than foliage; clings sideways and hangs upside-down, probes crevices in bark and branches; occasionally pursues insects in flight.

**Breeding.** Season Mar–Dec, possibly throughout year. Monogamous, solitary breeder. Nest a pad or small platform of grass and lichens, placed up to 4 m above ground in hole or cavity in tree trunk or stump; holes in walls of buildings occasionally utilized. Clutch 3–5 eggs; incubation by both sexes, and young fledge at c. 26 days. No other information.

**Movements.** Resident; vagrant to N Mozambique (at 570 m).

**Status and Conservation.** Not globally threatened. Generally common or locally common throughout its range.

**Bibliography.** Benson *et al.* (1959), Borrow & Demey (2001), Britton (1980), Carswell *et al.* (2005), Dowsett & Dowsett-Lemaire (1993), Dowsett-Lemaire & Dowsett (2006), Fry *et al.* (2000), Hall (1960), Hall & Moreau (1970), Harrap & Quinn (1996), Mackworth-Præd & Grant (1973), McCarthy (2006), Short *et al.* (1990), Sinclair & Ryan (2003), Stevenson & Fanshawe (2002), Zimmerman *et al.* (1996).

### 30. Southern Black Tit

#### *Parus niger*

French: Mésange nègre

German: Mohnenmeise

Spanish: Carbonero Negro

**Taxonomy.** *Parus niger* Vieillot, 1818, Sunday River, Eastern Cape Province, South Africa.

Forms a superspecies with *P. guineensis*, *P. leucomelas*, *P. carpi* and *P. albiventris*, possibly also including *P. leuconotus*. Has been considered conspecific with *P. leucomelas*, but the two appear not to interbreed in area of range overlap in Malawi and Zambia. Races intergrade widely and boundaries imperfectly known. Three subspecies recognized.

**Subspecies and Distribution.**

*P. n. xanthostomus* Shelley, 1892 – SE Angola, C & S Zambia, SW Tanzania, NE Namibia, N & E Botswana and N South Africa (North West Province).

*P. n. ravidus* Clancey, 1964 – E Zambia, Malawi, Zimbabwe and C Mozambique S to extreme N South Africa (N Limpopo Province).

*P. n. niger* Vieillot, 1818 – S Mozambique S to Swaziland and E South Africa (S to Eastern Cape).

**Descriptive notes.** 15–16 cm; 17.2–26 g. Large black tit with white in wing. Male nominate race has entire body black (in fresh plumage, crown to uppertail-coverts glossed bluish), tail black, all feathers glossed bluish on fringes and with narrow whitish tips, outermost rectrix broadly fringed and tipped white; lesser upperwing-coverts sooty brown, tips of longer lesser coverts white, median coverts white, greater coverts with dark centres and white fringes, alula and primary coverts black, finely fringed or tipped white; flight-feathers sooty brown, lower tertial broadly fringed white, secondaries narrowly fringed white, primaries the

same or white fringes narrower; side of throat and breast slightly glossed, belly and flanks paler or tipped grey-brown, undertail-coverts broadly tipped white; axillaries sooty black, underwing-coverts black with white tips; in worn plumage duller, white tips on tail abraded, darker centres of greater coverts more extensive, white on tertials also abraded or absent; iris brown; bill black; legs dark slate-grey to blue-grey or grey. Differs from *P. carpi* in slightly larger size, longer tail, less white in wing, slightly greyer underparts, prominently barred undertail-coverts, more white on tips of tail and edge of outermost rectrix. Female is very like male, but less glossy on upperparts, paler or greyer below, breast and belly ash-grey, slightly darker on side of breast, undertail-coverts grey with broad white tips. Juvenile is similar to adult, but dark brown above, tail finely fringed paler brown and outermost rectrix broadly fringed and tipped white, wing feathers darker brown with fringes dull off-white or yellowish, underparts dull greyish-brown, becoming paler on lower belly, undertail-coverts dingy brown with off-white tips. Racial variation slight: *ravidus* is as nominate, but white edges on wings broader and more extensive, forming complete panel on inner greater coverts, greyish wash on flanks more extensive, female has slightly paler or bluish-grey underparts; *xanthostomus* is also as nominate, but both sexes have slightly paler underparts (but darker than previous), especially breast side, flanks and undertail-coverts. **Voice.** Fairly noisy (especially when predator in vicinity), and group-members frequently give nasal, buzzing contact notes, “jee-jee-jee-jee-jee”, “tsi-tsi-chacha” or “tit-si-chachacha”, also a grating “jrr-jrr-jrr...” and harsher “chrrr-chrrr-chrrr”; other calls include high-pitched “chew-ri, chew-ri, chew-ri” and softer or more mellow “peeoo-pu-peeoo” or “cheru-cheru-cheru” and musical “phee-cher, phee-cher”. Song a combination of various call notes repeated in short series, “chip-we, chip-we, chip-we, pi-cher, pi-cher, pi-cher, tiroo, tiroo, tiroo, peetit-woo, peetit-woo, peetit-woo, pee-wirrit, pee-wirrit, pee-wirrit...”, occasionally interspersed with harsher grating or churring notes.

**Habitat.** Wide variety of broadleaf mopane (*Colophospermum*) and miombo (*Brachystegia*) woodland and savanna woodland, including dry woodland and thickets of *Baikiaea*, *Combretum* and *Burkea*, mopane and mixed deciduous woodland, dry miombo and acacia (*Acacia*) thorn-scrub; occurs also in parks and suburban gardens; largely replaced by *P. rufiventris* in brachystegia woodland in areas where the two overlap in range. Usually below 1070 m.

**Food and Feeding.** Diet during breeding principally lepidopteran larvae (including those with toxic hairs); in non-breeding season also other small invertebrates, including beetles (Coleoptera), earthworms (Oligochaeta), moths (Lepidoptera) and spiders (Araneae), also seeds and some fruit, including figs (*Ficus*) and mistletoe (Loranthaceae) berries; also drinks nectar of aloes (particularly *Aloe barberae* and *Aloe ferax*). Usually in pairs or in small groups (probably family parties); in non-breeding season in mixed-species flocks, which roam widely, up to 10 km per day, in search of food. Forages in upper and middle levels of trees, examining foliage (particularly partly eaten leaves for signs of caterpillars), and searching bark and trunk for prey. Will tear off bark strips or lichen; taps dry seedpods, especially of *Combretum* (apparently able to identify those with chalcid wasp larvae), and noisily discards pieces of the husks. Hawks termites (Isoptera) in flight, returning to perch to eat prey.

**Breeding.** Season Aug–Jan; one brood. Monogamous; estimated c. 66% of population have co-operative breeding system, whereby dominant pair assisted in territory defence and brood-rearing by up to three male helpers, probably young from earlier brood (at study site in N South Africa 58% of nests had helpers). Territory used throughout year, may be shared with at least one other pair, male present within territory for most of year, defends it against interlopers (including helpers, until incubation begins) with excited calling, occasionally leading to chasing and physical aggression. Display involves courtship-feeding of female by dominant male, which also chases helpers from female during pre-laying period. Nest built entirely by female, a small, thick pad or

platform of fine plant fibres, lichens and animal hair, placed 2–5 m above ground in natural hole or cavity in tree trunk, occasionally (less frequently than with other tits in region) old hole of woodpecker (Picidae) or barbet (Capitonidae) utilized, or hole in fence post or nestbox used; size of territory depends on numbers of pairs present, 25–30 ha for single pair and 36–48 ha for up to four adults. Clutch 4–5 eggs; incubation by female, fed by male and any helpers present, period 14–15 days; chicks fed by both sexes and by helpers, nestling period up to 24 days; young able to feed themselves after a further 7 days, but also fed by adult female and helpers for up to 40 days; young remain within group’s territory for up to 9 months, before dispersing. Nests occasionally parasitized by Greater Honeyguide (*Indicator indicator*). At study site in South Africa, 13 breeding groups (comprising 13 females and 22 males) successfully fledged 16 young; pairs with helpers generally more successful than those without. Breeds in first year. Of 13 females and 22 males in breeding groups at South African study site, three females and five males survived to following breeding season.

**Movements.** Resident.

**Status and Conservation.** Not globally threatened. Common or locally common. Population in South Africa estimated at 10,000,000 individuals and in S Mozambique estimated c. 500,000 individuals; density of 45 individuals in 400 ha in South Africa (N Limpopo Province).

**Bibliography.** Clancey (1972b, 1996b), Dowsett & Dowsett-Lemaire (1993), Dowsett-Lemaire & Dowsett (2006), Fry *et al.* (2000), Gill *et al.* (2005), Ginn *et al.* (1989), Hall & Moreau (1970), Harrap & Quinn (1996), Harrison *et al.* (1997), Hockey *et al.* (2005), Irwin (1981), Mackworth-Præd & Grant (1963), Maclean (1993), McCarthy (2006), Newman (1989), Penry (1994), Sinclair & Ryan (2003), Sinclair *et al.* (2002), Tarboton (1981).

### 31. Carp’s Black Tit

#### *Parus carpi*

French: Mésange de Carp

German: Carpmoise

Spanish: Carbonero de Carp

Other common names: Carp’s Tit

**Taxonomy.** *Parus niger carpi* Macdonald and B. P. Hall, 1957, Warmquelle, Kaokoveld, Namibia. Forms a superspecies with *P. guineensis*, *P. leucomelas*, *P. niger* and *P. albiventris*, possibly also including *P. leuconotus*. Has been considered conspecific with *P. leucomelas* and *P. niger*; further research required. Monotypic.

**Distribution.** SW Angola and N & W Namibia.

**Descriptive notes.** 15 cm; 17.2–20.3 g. Large, black tit with extensive areas of white in wing. Male has entire body black (in fresh plumage, crown to uppertail-coverts glossed bluish), tail black, all feathers glossed bluish-black on fringes and outer three feathers narrowly tipped white; upperwing-coverts black, lesser and median coverts tipped white (forming solid panel), greater coverts fringed (or more broadly tipped) white except for inners, which are mostly white; alula and primary coverts black, finely fringed or tipped white, flight-feathers blackish-brown, fringes of upper tertials glossy bluish, white on lowest tertial, secondaries

broadly fringed and tipped white (forming broad white panel on closed wing), primaries narrowly fringed white or whitish; slightly glossed on neck side to belly, less visibly so on flanks, undertail-coverts narrowly fringed whitish (appear uniform blackish in field); axillaries and underwing-coverts black, tipped white; in worn plumage, duller (less glossy) overall, white in wing duller and abraded, revealing darker centres of greater coverts; iris dark brown or brown; bill black, paler edges; legs grey, bluish-grey or black. Distinguished from *P. niger* mainly by slightly smaller size, shorter tail and smaller bill, generally more intensely black colour, especially on underparts, less white on tips and side of tail, broader white fringes on inner greater and all median wing-coverts; from *P. leucomelas* by less solid white patch in wing, black centres of outer greater coverts. Female is very like male, but duller or browner on face to throat, and fringes of greater coverts and flight-feathers slightly narrower. Juvenile is as adult, but blackish-brown above, slightly glossed blue on crown, mantle, scapulars and breast (less so on female), wing and tail browner, white on flight-feathers replaced by buffish-yellow, tail feathers lack white at tips. **Voice.** Calls include grating “jer-jer-jer-jer...” as contact (also as “tsi-tsi-tsi-jer-jer-jer...”), also a fairly musical “churia-churia-churia” and a whistled “piu-piu-piu-piu-piu...”, “wich-a, wich-a, wich-a...” and harsher or rasping “tsi-ysi, tsi-cha-cha-cha-cha”. All calls very similar to those of *P. niger*.

**Habitat.** Savanna and acacia (*Acacia*) woodland and dry mopane thickets and woodland, usually with scrubby undergrowth, generally along watercourses in broken or hilly areas; near coast in SW Angola occurs in tangled thickets in dense grassland. Occasional visitor in suburban gardens in non-breeding season. Normally found above 1000 m in Namibia, and at c. 1220–1830 m in S Angola.

**Food and Feeding.** Food not well studied, but known to include small invertebrates, principally spiders (Araneae), ants (Hymenoptera) and termites (Isoptera), also moth larvae (Lepidoptera). Usually in pairs, occasionally solitary; in non-breeding season in small groups of up to six individuals, also joins mixed-species foraging flocks. Active and acrobatic. Forages in large to medium-sized thorn trees and smaller bushes, where it searches foliage and branches for prey; noisily pecks or hammers at seedpods. Fairly restless, and moves quickly from tree to tree in undulating flight.

**Breeding.** Season Oct–May, also Jul, timing influenced by onset of rains and may not breed in drought years; one brood. Monogamous; helpers (usually males) feeding young reported at some nests. Territory usually (not always) occupied throughout year. Male courtship-feeds female, during which both partners quiver wings. Nest built entirely by female, an untidy thick cup or pad of soft plant down, grasses, strips of discarded snakeskin, animal hair and feathers, placed in natural hole or cavity in tree, occasionally in old hole of woodpecker (Picidae) or barbet (Capitonidae), or open pipe or nestbox used. Clutch 4–5 eggs; incubation by female, fed at nest by male, period 13–15 days; chicks leave nest at c. 18 days, fed by parents for at least the following 3–4 days. Breeding success largely dependent on rainfall: in Namibian study of 14 nests, 5 failed owing to desertion during hot, dry weather, and 9 produced at least 1 fledgling each, although 4 of these suffered some predation of nestlings.

**Movements.** Resident.

**Status and Conservation.** Not assessed. Considered to be uncommon or locally common. Global population estimated at between 409,580 and 577,520 individuals.

**Bibliography.** Boix-Hinzen *et al.* (2002), Clancey (1972b, 1995), Fry *et al.* (2000), Ginn *et al.* (1989), Hall (1960), Harrap & Quinn (1996), Harrison *et al.* (1997), Hockey *et al.* (2005), Jarvis & Robertson (1999), Mackworth-Præd & Grant (1963), Maclean (1993), Osborne (2001), Sinclair & Ryan (2003), Sinclair *et al.* (2002), Wiggins (2001).

# Family PARIDAE (TITS AND CHICKADEES)

## SPECIES ACCOUNTS

### 32. White-bellied Tit

#### *Parus albiventris*

**French:** Mésange à ventre blanc **German:** Weißbauchmeise **Spanish:** Carbonero Ventri blanco  
**Other common names:** White-breasted Tit

**Taxonomy.** *Parus albiventris* Shelley, 1881, Ugogo, northern Tanzania.

Forms a superspecies with *P. guineensis*, *P. leucomelas*, *P. niger* and *P. carpi*, possibly also including *P. leuconotus*. Monotypic.

**Distribution.** SE Nigeria and C & W Cameroon; also SE Sudan, NE Uganda, W Kenya and Tanzania.

**Descriptive notes.** 14–15 cm. Large, black tit with white belly and much white in wing. Male has entire head and upperparts, including tail, black, in fresh plumage glossed bluish; tail narrowly tipped white, and outer feathers fringed white (broadest or most white on outermost); lesser upwing-coverts black, tips of longest ones white, median coverts white, greater coverts black, broadly fringed white, alula black, finely fringed white; flight-feathers black, fringes of lower tertial white (may also be white on central tertial), secondaries narrowly fringed white, becoming more broadly fringed on inners (forming broken

white panel on closed wing), primaries also narrowly fringed white or whitish; chin to centre of breast black (black sometimes extending to upper flanks), slightly glossed blue, sharply demarcated from white rest of underparts; axillaries black, underwing-coverts white; in worn plumage, duller or browner on head and breast, and white in wing and tail abraded, revealing darker centres of feathers; iris dark brown or black; bill black; legs bluish-grey or black. Female is duller than male, sooty black or browner, less glossy, and underparts duller or greyer. Juvenile is as female, but sooty brown above, wings and tail sooty black, white on wing-coverts buff or washed yellowish, no white tips on tail, and throat may be slightly paler. **Voice.** Calls include harsh, nasal “si-chah-chah-chah”, often given with emphasis in scolding alarm, also a similar but thinner or more musical “tss-tss-tss, cher-cher-cher-cher”; contact calls include “twach-twach-twach” or “chrip-twisch-twach”, and also gives sharp “tss, tsee” phrases, often in longer series e.g. “tss, tss, tss, tsee”. Song, apparently infrequently heard, “chee-er-weeoo, chee-er-weeoo”, and a soft and repeated, warbling “pee-pee-purr”.

**Habitat.** In E Africa occurs in lightly bushed acacia (*Acacia*) woodland, edges of montane evergreen forest, riverine woodlands, grassland with scattered trees, orchards, edges of cultivation and large gardens, mostly above 1000 m and up to 3400 m; above 1600 m in SE Sudan. In Nigeria and Cameroon, found in highland savanna at 1070–2135 m.

**Food and Feeding.** Food not well known, but includes small invertebrates, e.g. spiders (Araneae), grasshoppers (Orthoptera) and larvae, also seeds, and possibly nectar. Solitary, in pairs or often in fairly large flocks; often one of the main components in mixed-species foraging flocks. Active and restless, with rapid flitting motion. Forages usually in canopy and middle levels of trees, also frequently descending to lower branches and undergrowth; investigates foliage, branches (including undersides), bark, clumps of lichens, and epiphytes in great detail.

**Breeding.** Poorly known. Probably breeds throughout year, but mainly during rains in Oct–Jan. Monogamous; territorial. Nest a small cup or pad, mostly of bark strips, lichen, animal hair, plant down and fibres, placed up to 8 m from ground in natural hole or cavity in decaying tree stump or behind loose bark, or may utilize old hole of woodpecker (Picidae) or barbet (Capitonidae); entrance to nest-hole usually a very narrow slit. Clutch 3–5 eggs; incubation period at least 12 days; young fledge at least 20 days after hatching.

**Movements.** Resident.

**Status and Conservation.** Not globally threatened. Common or locally common; rare in SE Nigeria, where confined to Obudu Plateau. Some evidence of reduction in range in Kenya, where thought to have occurred formerly along E coastal strip, parts of Tsavo East National Park and several arid areas in SE.

**Bibliography.** Borrow & Demey (2001), Britton (1980), Carswell *et al.* (2005), Elgood *et al.* (1994), Fry *et al.* (2000), Gill *et al.* (2005), Hall & Moreau (1970), Harrap (1996), Harrap & Quinn (1996), Lewis & Pomeroy (1989), Mackworth-Præd & Grant (1973), Short *et al.* (1990), Sinclair & Ryan (2003), Stevenson & Fanshawe (2002), Zimmerman *et al.* (1996).

### 33. White-backed Black Tit

#### *Parus leuconotus*

**French:** Mésange à dos blanc **German:** Weißrückenmeise **Spanish:** Carbonero Dorsiblanco  
**Other common names:** White-backed Tit

**Taxonomy.** *Parus leuconotus* Guérin-Méneville, 1843, Ethiopia.

Apparently closely related to, and possibly a member of, the superspecies formed by *P. guineensis*, *P. leucomelas*, *P. niger*, *P. carpi* and *P. albiventris*. Monotypic.

**Distribution.** Eritrea and Ethiopia.

**Descriptive notes.** 13.5–14 cm; 16–17 g. Medium-sized to large, small-billed black tit with creamy-white patch on upperparts. Male in fresh plumage has entire body, wing and tail sooty black, except for creamy-white mantle to upper back; crown to nape glossed deep blue, rest of upperparts, including wing, faintly glossed, tail feathers glossed bluish-black on fringes, fine narrow whitish tips on outermost three pairs; usually narrow white tips on tertials and secondaries, and white tips on undertail-coverts; in worn plumage, duller or browner, mantle patch greyer and occasionally smaller (restricted to side of mantle); iris brown; bill black; legs

dark slate-grey to black. Female has underparts duller or more sooty brown than male. Juvenile is slightly duller and browner than adult, lacking gloss, and mantle patch is duller or more buffish and may show darker feathers bases. **Voice.** Calls include buzzing “bee-bzz-bzz”, dry “tchu-chu-chu” like that of a sparrow (*Passer*), also often as single “tchu” note, also a thin “tsit”, and a liquid “plit”

or “quit” which may be run into longer series as “plit, tchiu-pdu, plit, tchiu-pdu...” or “pit-tyo-wheel...”; also variety of more typical tit-like phrases, including harsh “tzet-tzee-tzee, tzet-tzee-tzee-tzet” and more rapid “tsi-za-za-za”. Song a longer version of call-note phrases, often given with emphasis, e.g. “tchu, plit-kli, chu-eeu, tchu, plit-kli chu-ee-u” and “tit-teet-toraykeet, jit-jit”. **Habitat.** Principally in highland *Hagenia* forests, also mixed podocarp–juniper–olive (*Podocarpus–Juniperus–Olea*) forest at 1800–3200 m; also highland bamboo and giant heath at higher altitudes, to 3500 m. Has been recorded down to 1370 m near Jima, in SC Ethiopia.

**Food and Feeding.** Diet not well known, but includes small invertebrates, larvae and seeds. Solitary or in pairs; also in small loose groups. Actively forages in middle to upper levels of trees.

**Breeding.** Thought to breed in Jan, May and Aug, and female in breeding condition Dec, but no nests found. No other information. Maximum recorded longevity 8 years.

**Movements.** Primarily resident; some altitudinal movement. One ringed individual recovered 223 km from site where ringed.

**Status and Conservation.** Not globally threatened. Common or locally common in Ethiopia. In Eritrea was formerly uncommon, and possibly now extirpated; not seen since 1957. Present in Bale Mountains National Park (Ethiopia).

**Bibliography.** Ash (1994), Ash & Gullick (1989), Fry *et al.* (2000), Hall & Moreau (1970), Harrap (1996), Harrap & Quinn (1996), Mackworth-Præd & Grant (1973), Neumann (1906), Pol (2001), Rüppell (1845), Sinclair & Ryan (2003), Urban & Brown (1971).

### 34. Dusky Tit

#### *Parus funereus*

**French:** Mésange enfumée **German:** Einfarbmeise **Spanish:** Carbonero Cenizo

**Taxonomy.** *Melanoparus funereus* J. Verreaux and É. Verreaux, 1855, Gabon.

Has been considered part of the superspecies formed by *P. guineensis*, *P. leucomelas*, *P. niger*, *P. carpi* and *P. albiventris*, possibly also *P. leuconotus*, but is ecologically separated from all of these and all other African tits. Two subspecies recognized.

**Subspecies and Distribution.**

*P. f. funereus* (J. Verreaux & É. Verreaux, 1855) – Sierra Leone and Guinea E, discontinuously, to DR Congo, S Uganda, extreme S Sudan and W Kenya.

*P. f. gabela* T aylor, 1961 – W Angola.

**Descriptive notes.** 13–14.5 cm; 22–29 g. Medium-sized to large, all-dark tit with red eyes. Male nominate race has entire body, wing and tail blackish or sooty black, in fresh plumage crown to uppertail-coverts glossed bluish-green; upperwing-coverts glossed duller bluish-green, and flight-feathers slightly darker, outer primaries finely fringed greyish; axillaries blackish to dark-grey; in worn plumage, flight-feathers duller and browner; iris deep bright red to orange-red; bill black; legs bluish-grey or black. Female is similar to male, but has upperparts blackish-grey, brownish-grey feather tips on forehead to nape, upperparts duller and less

glossy than male, tail fringed grey-brown, greater coverts and flight-feathers also finely fringed greyer, face and underparts paler and greyer than male. Juvenile resembles male, with upperparts blackish-brown but lacking glossy tones, and with large white tips on greater coverts. Race *gabela* differs little from nominate, has throat to breast duller black, lacking greenish gloss, and female is paler, with underparts bluish slate-grey. **Voice.** Very vocal, and has wide variety of calls, including slow and ringing “see-er, see-er, see-er”, variably given as “ss-pyew” or “fui-tsiu” (Rwanda) or “see-tyop” (Liberia), also a metallic “chut-chut-tzi-tzi-tzi” and similar whistled “tsi-tsi-tsi-tu”, and a series of slow, harsh churrs, “tirru, tirru, tirru, turee, tirru”. Song apparently a longer and more varied version of the call notes, including slow, metallic and ringing “tsi-piu, tsi-piu, tsi-piu” or “tsi-pupu, tsi-piu, tsi-pupu, tsitsi-pu” and repeated “zi-zizi-huititi-tihui-tihui”, also described as a jumbled medley of harsh and whistled notes incorporating various call notes and churrs, together with occasional imitations of other birds, e.g. Fraser’s Forest-flycatcher (*Fraseria ocreata*).

**Habitat.** Dense primary and secondary evergreen forests, also gallery forest, old plantations and edges of cultivation; in Liberia occurs in forest–grassland mosaic at 550–800 m on Mt Nimba. Above 800 m in Guinea and to 2200 m in DR Congo; up to 2000 m in S Sudan (Imatong Mts), at 900–1700 m in Uganda and W Kenya, but to 2440 m in Impenetrable Forest (SW Uganda); to 2500 m (but more numerous below 2100 m) in Nyungwe Forest, in Rwanda; to 2500 m in W Angola.

**Food and Feeding.** Food includes small invertebrates, mainly beetles (Coleoptera) and orthopterans, also larvae, principally of micro-lepidopterans; also seeds and fruit. Usually in pairs, in family parties of 3–6 individuals, or in larger groups of up to 15; also often in (or leading) mixed-species foraging flocks. Single-species flocks occupy and defend territories of 12–15 ha. Actively forages in canopy, on boughs and around branches of tall trees, also clings to trunk, including of tall parasol trees (*Musanga*) in secondary forest; rarely descends to within 15 m of ground. Examines branches, clumps of dead leaves and bark for prey, occasionally in fruiting trees e.g. fig (*Ficus*).

**Breeding.** Poorly known. Season variable, possibly dependent on rains; adults in breeding condition in Nov in W Africa and Mar, Jun and Sept in DR Congo, and fledglings in Apr–Jul and Oct in W Africa and Oct in Uganda. One nest found, lined with soft plant material, placed 15 m from ground in hole in dead tree. Clutch 3 eggs; two juveniles begging for food 3 months after leaving nest. No other information.

**Movements.** Resident.

**Status and Conservation.** Not globally threatened. Locally common or uncommon in Guinea, Sudan and Uganda; scarce in Sierra Leone and Cameroon; rare in E Ivory Coast and S Ghana. Estimated density of 25–30 individuals/km<sup>2</sup> in NE Gabon. In Uganda, range formerly extended E to Mt Elgon. Entire population of W Angolan race *gabela* now confined to small area of evergreen forest, most of which has been replaced with coffee plantations.

**Bibliography.** Borrow & Demey (2001), Britton (1980), Brosset & Éard (1986), Carswell *et al.* (2005), Chapin (1954), Colston & Curry-Lindahl (1986), Dowsett-Lemaire & Dowsett (1998), Fry *et al.* (2000), Gatter (1997), Gill *et al.* (2005), Hall & Moreau (1970), Harrap & Quinn (1996), Lewis & Pomeroy (1989), Mackworth-Præd & Grant (1973), Short *et al.* (1990), Sinclair & Ryan (2003), Stevenson & Fanshawe (2002), Zimmerman *et al.* (1996).

### 35. Rufous-bellied Tit

#### *Parus rufiventris*

**French:** Mésange à ventre cannelle **German:** Rostbauchmeise **Spanish:** Carbonero Ventrirrufo

Other common names: Rufous Tit

**Taxonomy.** *Parus rufiventris* Bocage, 1877, Caconda, Angola.

Forms a superspecies with *P. pallidiventris* and *P. fringillinus*. Has been considered conspecific with former, but differs in eye colour (possibly age-related) and belly colour (varies clinally); hybridization not proven, and identity of supposed intermediates (based chiefly on eye coloration) uncertain; further research required. Races intergrade widely. Three subspecies recognized.

**Subspecies and Distribution.**

*P. r. rufiventris* Bocage, 1877 – S PR Congo and SW & S DR Congo S to C Angola and C Zambia.

*P. r. diligens* Clancey, 1979 – S Angola, N Namibia, SW Zambia and NW Botswana.

*P. r. masukuensis* Shelley, 1900 – SE DR Congo, E Zambia and Malawi.

**Descriptive notes.** 14–15 cm; c. 20 g. Large tit with pale eye, black head to breast and rufous underparts. Male nominate race has entire head to nape and neck side, throat and breast black, in fresh plumage glossed bluish; mantle, back and scapulars dark grey, rump and uppertail-coverts darker (blackish-grey); tail black, outer two feathers narrowly tipped white; upperwing-coverts black, broadly fringed and tipped white (narrowly edged on greater), alula black, primary coverts dark grey, finely fringed pale greyish and tipped white; flight-feathers black, all tertials broadly fringed and tipped whitish, secondaries and primaries finely fringed whitish; side of breast to centre of lower breast dark grey, rest of underparts dull rufous-orange; axillaries pale grey, underwing-coverts white; in worn plumage, pale fringes on wing become abraded and duller; iris sulphur-yellow or creamy; bill black; legs bluish-grey. Female is very like male, but has slightly paler rufous underparts. Juvenile is as adult but duller, with head to upper breast dark sooty grey, crown greyish, upperparts tinged brown, wings dark sooty brown, median and greater upperwing-coverts with buffish tips, edges of greater coverts narrower than on adult, flight-feathers fringed yellowish-buff, lower breast, belly and flanks pale chestnut, iris darker or greyer. Racial variation slight: *diligens* is as nominate, but head duller and grades into more blue-grey mantle, chin to throat less black and grading into grey on breast, female has duller hood merging with same colour on mantle and back, and has chin to upper throat grey; *masukuensis* is also as nominate, but has upperparts paler grey, throat blackish, breast paler grey, underparts paler or pinkish-cinnamon. VOICE. Calls include thin “sit, sit” and “sziit”, becoming part of longer series of “si-ch” or “tsitsi-chaa-chaa-chaa-chaa” or a more rolling “whit-cherr, whit-cherr, whit-cherr”; occasionally a sweeter or higher-pitched and frequently repeated “pet-tipio, pet-tipio, pet-tipio”; alarm a harsh, grating “churr-churr-churr”. Song very like a longer version of call notes, as well as rapid and ringing deliveries of typical tit-like notes, including “weetu-chu, weetu-chu”, “chick-wee, chick-wee, chick-wee”, “peetada, peetada, peetada...” or “pet-tida, pet-tida, pet-tida”.

**Habitat.** Open and mature mopane or miombo (*Brachystegia*) woodland, savanna with thorn-scrub, edges of dry evergreen forest and *Baikiaea* woodland, also mossy transitional woodland. Co-exists with *P. griseiventris* in mature miombo woodland (though the two species apparently occupy differing niches); occurs with *P. niger* in areas of dry woodland in NE Namibia, rarely elsewhere. Usually above 600 m or possibly slightly lower (down to L Nyasa, in Malawi); to 1725 m in DR Congo (most numerous at 1200–1500 m), to 1950 m in NE Zambia, and to c. 2000 m in Malawi (Nyika Plateau).

**Food and Feeding.** Diet principally small invertebrates and larvae. Usually in pairs, small groups or mixed-species flocks; occasionally in foraging flocks with *P. griseiventris*. Forages in middle and upper levels of trees, favouring large trees and those with heavy growth of lichens, especially *Usnea*; forages mostly among outer foliage and branches, where it gleans insect prey from outer leaves while clinging to slender twigs.

**Breeding.** Poorly known. Season Sept–Dec. Possibly a co-operative breeder, group of four individuals prospecting for nest-sites in Angola. Nest a cup or pad of grass and plant fibres, bark strips and animal hair, placed up to 3 m (exceptionally to 8 m) above ground in hole in tree trunk or old tree stump, often in old hole of woodpecker (Picidae) or barbet (Capitonidae). Clutch 3–4 eggs. No other information.

**Movements.** Resident.

**Status and Conservation.** Not globally threatened. Common or locally fairly common in DR Congo and Zambia; uncommon elsewhere. Rare, or irregular visitor, in NW Botswana. In Zambia, density of 2–1 individuals/10 ha of miombo woodland.

**Bibliography.** Alerstam & Ulfstrand (1977), Britton (1980), Clancey (1996b), Dowsett & Dowsett-Lemaire (1993), Dowsett-Lemaire & Dowsett (2006), Fry *et al.* (2000), Gill *et al.* (2005), Ginn *et al.* (1989), Hall & Moreau (1970), Harrap & Quinn (1996), Harrison *et al.* (1997), Hockey *et al.* (2005), Irwin (1981), Mackworth-Præd & Grant (1963, 1973), Maclean (1993), McCarthy (2006), Newman (1989), Penry (1994), Sinclair & Ryan (2003), Sinclair *et al.* (2002), Stevenson & Fanshawe (2002).

## 36. Cinnamon-breasted Tit

### *Parus pallidiventris*

**French:** Mésange à œil jaunâtre **German:** Zimtbauchmeise **Spanish:** Carbonero Ventripálido

**Taxonomy.** *Parus pallidiventris* Reichenow, 1885, Kakoma, Tabora district, Tanzania.

Forms a superspecies with *P. rufiventris* and *P. fringillinus*. Has been considered conspecific with former, but differs in eye colour (possibly age-related) and belly colour (varies clinally); hybridization not proven, and identity of supposed intermediates (based chiefly on eye coloration) uncertain; further research required. Races intergrade in Mozambique. Two subspecies recognized.

**Subspecies and Distribution.**

*P. p. pallidiventris* Reichenow, 1885 – Tanzania, S Malawi and N Mozambique.

*P. p. stenotopicus* Clancey, 1989 – E Zimbabwe and WC Mozambique.

**Descriptive notes.** 15 cm. Large tit with dark eye, black head to breast and pale pinkish underparts. Male nominate race has entire head to nape and neck side, throat and centre of breast black, in fresh plumage slightly glossed bluish; mantle, back and scapulars dark grey, rump slightly paler grey, blackish shaft streaks on uppertail-coverts; tail black, all feathers narrowly fringed and tipped white; upperwing-coverts black, fringed and more broadly tipped white, alula black, primary coverts blackish, finely fringed and tipped pale greyish; flight-feathers black or blackish-grey, tertials broadly fringed and tipped whitish, secondaries and primaries finely fringed whitish, bases of outer primaries more broadly edged whitish (forming small patch); breast side to centre of lower breast dark grey, rest of underparts pale pinkish-buff, washed greyish; axillaries pale grey, tipped whitish, underwing-coverts white; in worn plumage, fringes of wing-coverts and flight-feathers abraded; iris brown to deep brown; bill black; legs light blue to bluish-grey. Female differs from

## Family PARIDAE (TITS AND CHICKADEES) SPECIES ACCOUNTS

male only in having slightly browner chin to breast. Juvenile has head to breast more sooty brown, or slightly paler brown on throat to upper breast, upperparts tinged brown, tail dark brown, wings dark sooty brown, median and greater coverts with broad off-white tips, edges of greater coverts narrower than on adult, secondaries and primaries fringed dingy yellowish-white, underparts paler and duller than adult, iris darker. Racial variation slight: *stenotopicus* has head duller or browner than nominate, mantle greyer, wing-coverts more broadly fringed and tipped white, white at base of outer primaries more extensive, black on

throat more sharply demarcated from grey of breast, lower breast paler grey, rest of underparts variably reddish to pinkish-buff. Voice. No information; calls and song apparently indistinguishable from those of *P. rufiventris*.

**Habitat.** Miombo (*Brachystegia*) and mahobohobo (*Uapaca*) woodland and wooded savanna, often with scattered thorn-scrub; at 490–670 m in Tanzania, 760–1525 m in Malawi, 275–840 m (but up to 1400 m on Mt Namuli) in Mozambique, and 500–1600 m in E highlands of Zimbabwe.

**Food and Feeding.** Diet not well known, but includes small invertebrates and larvae, also seeds and fruit. Usually in pairs or in groups of 3–4 individuals (possibly two pairs); also joins mixed-species foraging flocks, and in miombo woodland often found in close association with *P. griseiventris*. Forages mostly in upper and canopy levels of trees and scrub.

**Breeding.** Poorly known. Season Sept–Dec. Nest a pad or cup of grasses, plant fibres and bark strips, placed in hole in tree or stump. Clutch 4 eggs. No other information.

**Movements.** Resident.

**Status and Conservation.** Not assessed. Fairly common in N of range; less common or uncommon in Zimbabwe. Possibly present also in E Zambia; further research and fieldwork required.

**Bibliography.** Britton (1980), Dowsett & Dowsett-Lemaire (1993), Friedmann & Loveridge (1937), Fry *et al.* (2000), Hall & Moreau (1970), Harrap & Quinn (1996), Irwin (1981), Mackworth-Præd & Grant (1973), McCarthy (2006), Short *et al.* (1990), Sinclair & Ryan (2003), Sinclair *et al.* (2002), Stevenson & Fanshawe (2002), Zimmerman *et al.* (1996).

## 37. Red-throated Tit

### *Parus fringillinus*

**French:** Mésange à gorge rousse **German:** Rostkehlmeise **Spanish:** Carbonero Gorjirrufo

**Taxonomy.** *Parus fringillinus* G. A. Fischer and Reichenow, 1884, Mount Meru, Arusha, Tanzania. Forms a superspecies with *P. rufiventris* and *P. pallidiventris*. Monotypic.

**Distribution.** S Kenya and N & C Tanzania.

**Descriptive notes.** 11.5–12 cm. Small to medium-sized grey tit with rufous face, dark cap and white in wings. Male has bright rufous (sometimes tinged buffish) from forehead narrowly over eye to face, hindneck, neck side and chin to breast, dark grey or blackish crown to nape (may be finely fringed paler or greyer in fresh plumage); upperparts medium to dark grey; tail black, all feathers narrowly tipped white, outer two with white outer edge; upperwing-coverts dark greyish to black, broadly tipped white on medians and fringed and tipped white on greater, alula and primary coverts finely fringed pale greyish to off-white;

flight-feathers blackish-grey, tertials broadly fringed and tipped white, secondaries and primaries narrowly fringed white; side of breast to belly and vent buffish-grey, flanks and undertail-coverts slightly greyer, the latter tipped broadly whitish; axillaries and underwing-coverts pale grey; in worn plumage, cap darker, fringes and tips of wing feathers narrower; iris brown to deep brown; bill blue-grey to blackish, dark tip of upper mandible; legs bluish-grey to black. Female is as male, but has slightly paler rufous-buff forehead and face to breast. Juvenile is as female, but cap greyer and less well defined, with broad cinnamon or buffish edges, less white in tail. VOICE. Calls include variable “chick” or “pick”, variably plaintive, squeaky or explosive, also a softer but longer series of same note as “chick-chick, chick-chick-chick, chick-chick-chick...”, also “chachawi-chachawi-chachawi” and a typical parid “prtt-tchay-tchay-tchay” recalling similar notes of *Poecile montanus*; also a drawn-out series of “see-er” notes and a more buzzing “bzee-zee-zee”, and a harsh or scolding “ch-ch-ch” or longer “chrrrr”, which may be given with a thinner “si”, “tsi” or “sit” or a harsh “zwi-zwi-zwi”.

**Habitat.** Open acacia (*Acacia*) woodland, principally *Acacia xanthophloea*, and bushy and partly wooded savanna, also riverine woodland; usually at 1000–1600 m, exceptionally to 2000 m.

**Food and Feeding.** Food items include small invertebrates and larvae, also seeds and fruit. Occurs singly, in pairs or in small groups. Conspicuous and often very vocal, with frequent contact calls. Forages in all levels of trees and shrubs, moving slowly through foliage and vegetation, inspecting the foliage and bark.

**Breeding.** Poorly known. Season unclear, breeding recorded in Jan, Feb, Apr and Aug–Sept; may breed throughout year, with main frequency determined by rainy season. Only a single nest found, mostly of soft plant down and fibres, placed in cavity behind loose bark of tree; contained 3 eggs. No other information.

**Movements.** Resident.

**Status and Conservation.** Not globally threatened. Uncommon or locally common. Fairly common in Masai Mara, in S Kenya; fairly common also in Serengeti and Arusha National Parks, in N Tanzania.

**Bibliography.** Britton (1980), Collar *et al.* (1994), Friedmann & Loveridge (1937), Fry *et al.* (2000), Harrap & Quinn (1996), Lewis & Pomeroy (1989), Mackworth-Præd & Grant (1973), Short *et al.* (1990), Sinclair & Ryan (2003), Stevenson & Fanshawe (2002), Zimmerman *et al.* (1996).

## 38. Stripe-breasted Tit

### *Parus fasciiventer*

**French:** Mésange à ventre strié

**German:** Schwarzbrustmeise

**Spanish:** Carbonero del Ruwenzori

**Taxonomy.** *Parus fasciiventer* Reichenow, 1893, Ruwenzori Mountains, on DR Congo–Uganda border.

Has been considered part of the *P. afer* superspecies; probably closest to that group, but distinct morphologically and in habitat preferences. Nominate race and *tanganjicae* intergrade in SW Rwanda. Three subspecies recognized.

**Subspecies and Distribution.**

*P. f. fasciiventer* Reichenow, 1893 – Ruwenzori Mts (E DR Congo and W Uganda) and S in mountains to W Rwanda, highlands W of L Kivu and W Burundi.

*P. f. tanganjicae* Reichenow, 1909 – Itombwe Mts, in SE Kivu (E DR Congo) and SW Rwanda (Nyungwe forest).

*P. f. kaboboensis* Prigogine, 1957 – Mt Kabobo, in extreme SE Kivu (E DR Congo).

**Descriptive notes.** 14 cm; 14–15 g. Large tit with black head, and black stripe on white belly. Male nominate race has entire head to nape, neck side, throat and breast black, this colour tapering onto centre of upper belly (in fresh plumage, faintly glossed bluish on crown, nape, throat and breast); upperparts grey, washed brown, tips of longest uppertail-coverts blackish; tail black, narrowly tipped white (white may be lacking on central pair), outermost feather broadly edged white; upperwing-coverts black, fringed and more broadly tipped white, alula black, narrowly fringed whitish; flight-feathers black or blackish-grey, tertials

broadly fringed and tipped whitish, secondaries and primaries finely fringed whitish, bases of outer primaries more broadly edged whitish (forming small patch); side of lower breast to flanks and undertail-coverts white, duller or brownish on flanks; axillaries and underwing-coverts white; iris reddish-brown to deep brown; bill black; legs bluish-grey to slate-grey or greenish. Female has slightly browner head to breast and upper belly than male. Juvenile is as adult, but head to breast more sooty brown or duller brown (with blackish feather bases on throat, neck side and upper breast), narrow blackish stripe on centre of upper belly, rest of underparts tinged buffish or yellowish, upperparts tinged browner, less white at tips of tail, also tips of median and greater coverts yellowish-buff, edges of secondaries and primaries dingy yellowish-white. Race *tanganjicae* is as nominate female, but male has head to breast browner, with more obvious small black cap, blackish-grey on centre of throat down to belly stripe, rest of underparts more heavily washed buffish; *kaboboensis* has head and breast to centre of belly as nominate (female has paler brown breast), but upperparts more visibly washed bluish-grey, and rest of underparts darker grey except for whiter undertail-coverts. VOICE. Calls include soft “whit” or “whip” contact note and sharp or more strident “chit” or “tit”, also lower-pitched “dzer” or grating “grrr” or trilling “tittitrrrrrrr” that may be included in longer sequence e.g. “tittit-grr-ti-grr”, or with ringing “pseet” into longer series as e.g. “chit-chit-char-char, pseet char-char, chi-chit-char, chit-chit-char-char...”, or “chur-chur-chur-chur”; also gives thin “chit-lilit”; in alarm a short “chrit” note, often extended into longer scolding “chrit-it-it-it-it-it...” and may be combined in distinctive frog-like “chrit-chit-chit crud-y crud-y chrit-it-it-it-it-it!”. Song a repeated “tea-cher” phrase, like that of *P. major*.

**Habitat.** Montane forests, including *Hagenia* woodland, with bamboo and well-developed undergrowth; also tree-heath and gallery forest. Highlands and mountains; in Uganda at 1800–3400 m, and SW Rwanda widespread above 2300 m in Nyungwe Forest.

**Food and Feeding.** Diet poorly known, but presumably includes small invertebrates and larvae; nestlings fed mainly with caterpillars. Usually in small to medium-sized groups of presumed family parties; occasionally in mixed-species foraging flocks with *P. funereus* and white-eyes (*Zosterops*). Fairly tame and approachable. Forages usually in upper or canopy level, also visiting smaller trees along forest edge and in clearings; may descend to lower levels of trees, but rarely in forest undergrowth. Feeds in busy probing fashion among foliage, including dead leaves and branches suspended in canopy, and creepers; also probes bark.

**Breeding.** Not well known. Season possibly Feb–Jul; birds in breeding condition in Nov in DR Congo and Dec–Jan in Uganda, nestling in Dec in Uganda, and family parties containing both dependent and independent juveniles in Oct in Rwanda, the latter indicating possibility of two broods. Monogamous; possibly a co-operative breeder, as additional birds seen to attend nestbox where pair nesting. Territorial. Only three nests documented, mostly of dry *Usnea* lichens and strips of discarded snakeskin, all in nestboxes. Clutch 3 eggs; nestlings brooded by female and fed mostly by male. No other information.

**Movements.** Resident, endemic to the Albertine Rift mountains.

**Status and Conservation.** Not globally threatened. Restricted-range species: present in Albertine Rift Mountains EBA. Common to locally very common. Although it is not presently at risk, any large-scale destruction or diminution of the forests within this species’ small range would possibly create a long-term threat to its survival.

**Bibliography.** Alerstam & Ulfstrand (1977), Britton (1980), Carswell *et al.* (2005), Dehn & Christiansen (2001), Fry *et al.* (2000), Gill *et al.* (2005), Hall & Moreau (1970), Harrap & Quinn (1996), Mackworth-Præd & Grant (1973), Shaw (2001b), Sinclair & Ryan (2003), Stevenson & Fanshawe (2002).

## 39. Somali Tit

### *Parus thruppi*

**French:** Mésange somalienne **German:** Somalimeise **Spanish:** Carbonero Somali  
**Other common names:** Acaia Tit, Northern Grey Tit

**Taxonomy.** *Parus thruppi* Shelley, 1885, south of Burao, north-west Somalia.

Forms a superspecies with *P. griseiventris*, *P. cinerascens* and *P. afer*. Has been considered conspecific with either one or both of last two, but differs morphologically, and is separated geographically from both by *P. griseiventris*. Nominate race intergrades with *harakae* in N Kenya. Two subspecies recognized.

**Subspecies and Distribution.**

*P. t. thruppi* Shelley, 1885 – S & E Ethiopia, Somalia (except SW) and N Kenya.

*P. t. barakae* F. J. Jackson, 1899 – extreme E Uganda, Kenya, SW Somalia (Gedo) and NE Tanzania.

**Descriptive notes.** 11.5–12 cm; 12 g. Small grey tit with large white face patch and black cap, bib and ventral stripe. Male nominate race has forehead and upper lores blackish, tipped buffish, crown and crown side (to below eye), nape and side of neck black, in fresh plumage slightly glossed bluish, small off-white patch on lower nape; upperparts grey, washed slightly buffish, longest uppertail-coverts tipped blackish; tail black, all feathers except central pair narrowly tipped white, broadest on outermost; upperwing-coverts sooty black, fringed and more broadly tipped white,

alula and primary coverts black, finely fringed and tipped whitish; flight-feathers black, tertials fringed whitish on outer edge, secondaries and primaries finely fringed whitish; cheek and ear-coverts white; chin, throat and centre of upper breast black, continuing as narrow black line to vent (may show irregular white tips on throat, upper breast and ventral line), narrow white border to black on breast and upper belly; sides of lower breast and belly pale buffish (sometimes tinged pinkish) to greyish, undertail-coverts fringed whitish; axillaries pale grey, underwing-coverts off-white; in worn plumage, forehead, crown and nape

duller, upperparts duller grey, less white at tips of tail, fringes of wing feathers abraded; iris brown to reddish-brown; bill dark slate or black; legs bluish-grey to black. Differs from very similar *P. griseiventris* in having broad black on sides of neck (enclosing white on face), slightly broader black bib. Female is like male, but slightly duller and less extensive black on chin to breast. Juvenile resembles adult, with lower forehead pale buffish, crown to nape sooty brown, upperparts tinged duller brown, tail darker brown without white at tips, wings dark sooty brown, median and greater coverts with broad off-white tips, edges of greater coverts narrower than on adult, chin to centre of upper breast sooty brown, ventral line usually absent, rest of underparts duller; first-year separable from adult by mixture of old and new wing-coverts and flight-feathers. Race *barakae* is similar to nominate, but upperparts slightly paler, nuchal spot smaller or absent, breast side and border of ventral line broader and whiter, flanks pale grey with faint buff tinge. VOICE. Calls include buzzy “chya chya”, soft but hoarse “chet” or “chut”, often as longer “chet-chet-chet” series, also “tsi-tsa-char” and an explosive “tsi-tsi-chay-chay-chay” or “tsi-tsi-de-de-de-de-de”; also “si-ta-tcharr” and “tsia-tsia, tsia-tsia” with first note slurred or drawn out to a series of “tis-si-si-si”; also a nasal, rasping “chewy chewy chewy” or harsher “tchwa tchwa” and a rambling jumble of notes. Song a pleasant “see-uu” or “tuwee” with emphasis on second syllable, repeated up to six times, and a more typical “twee-tew-tew-tew” or “tsi-tsi-tchuerr-tchuerr-tchuerr”.  
**Habitat.** Mainly dry or arid open acacia (*Acacia*) woodland and *Commiphora* scrub, bushed grassland (but generally avoiding driest areas), also trees along watercourses. To at least 1400 m and possibly to 2000 m in Ethiopia, to 1000 m and locally to 1600 m in NW & C highlands of Kenya, and to 1500 m in Tanzania; in Somalia, up to 1950 m in N but inhabits lowlands in S.

**Food and Feeding.** Diet poorly known, but includes small invertebrates, principally wasps (Hymenoptera), beetles (Coleoptera) and larvae. Usually in pairs or in small to medium-sized groups of presumed family parties; often in mixed-species foraging flocks. Behaviour little known; appears to forage mostly in upper levels of trees, inspecting the bark and branches.

**Breeding.** Very poorly known, and few nests found. Season Feb–Jun. Territorial. Nest placed 2.5–7 m from ground in hole in dead tree. Clutch possibly 2 eggs. No other information.

**Movements.** Resident; vagrant in NE Uganda.

**Status and Conservation.** Not globally threatened. Uncommon to locally common. Poorly known species.

**Bibliography.** Archer & Godman (1961), Ash & Miskell (1998), Britton (1980), Carswell *et al.* (2005), Dowsett & Dowsett-Lemaire (1993), Fry *et al.* (2000), Granvik (1934), Hall & Moreau (1970), Harrap & Quinn (1996), Lewis & Pomeroy (1989), Mackworth-Præd & Grant (1973), Short *et al.* (1990), Sinclair & Ryan (2003), Stevenson & Fanshawe (2002), Zimmerman *et al.* (1996).

## 40. Miombo Tit

### *Parus griseiventris*

**French:** Mésange à ventre gris **German:** Graubauchmeise **Spanish:** Carbonero del Miombo  
**Other common names:** Miombo Grey/Northern Grey/Tabora Grey Tit

**Taxonomy.** *Parus griseiventris* Reichenow, 1882, Kakama, Tabora District, Tanzania.

Forms a superspecies with *P. thruppi*, *P. cinerascens* and *P. afer*. Has been considered conspecific with *P. cinerascens*. Paler birds from Zambia described as race *lundarum*, and birds from Mozambique and Zimbabwe with more prominent nuchal spot as *parvirostris*; definition and geographical delimitation of these, however, considered unpracticable. Treated as monotypic.

**Distribution.** Angola, S & SE DR Congo, and W Tanzania S to Zambia, Zimbabwe and NW Mozambique.

**Descriptive notes.** 14–15 cm. c. 20 g. Large black, white and grey tit. Male has forehead, crown and crown side (to below eye) and nape black, faintly glossed bluish in fresh plumage, small greyish-white patch on lower nape (sometimes absent), in Zimbabwe and N Mozambique nuchal patch typically more clearly defined (“*parvirostris*”); upperparts grey, longest uppertail-coverts tipped blackish; tail black, all feathers except central pair narrowly tipped pale grey, outer three pairs fringed pale grey, broadest on outer web of outermost; upperwing-coverts black, medians and greater coverts fringed and broadly tipped white, alula and

primary coverts black, finely fringed whitish; flight-feathers black, tertials fringed broadly whitish on outer edge and narrowly on inner edge, secondaries and primaries finely fringed whitish; cheek, ear-coverts and side of neck dull whitish to buffish; chin and throat (including side of throat) sooty black, black continuing as narrow line to centre of belly (may show occasional or irregular white tips on throat, upper breast and ventral line), side of lower breast and belly pale off-white, flanks greyish, undertail-coverts grey with whitish fringes; axillaries pale grey, underwing-coverts off-white; variation includes birds in Zambia with nuchal patch well defined, usually paler grey upperparts, white tips on median coverts broader, and underparts creamy-white with buffish-grey wash on breast side and flanks (“*lundarum*”); in worn plumage, crown and nape duller, upperparts slightly duller or browner, fringes of wing feathers abraded; iris brown to grey-brown or dark brown; bill black; legs greyish to black. Distinguished from very similar *P. thruppi* by larger size, lack of black on neck side (white on face meets that on side of neck); from *P. cinerascens* by smaller bill, duller cap, paler grey plumage, whiter underparts. Female is like male, but has slightly duller (less glossy) crown, and slightly less black and less extensive bib. Juvenile is as female, but outer tail feathers only narrowly fringed and without white at tips, wings dark sooty brown, edges of flight-feathers washed yellowish-buff, cheek duller or more buffish, bib duller sooty brown,

ventral line usually absent. Voice. Most frequent call "chitji", sometimes accompanied by loud "chip", also a harsh or deep "chrrr-chrrr-chrrr-chrrr" often preceded by thin "si", "sisi", "tit" or "plit", occasionally with more squeaky "tit-tieu"; rolling "swip-ji-ji-ji-ji" and chattering or scolding "tjou-tjou-tjou-tjou", also a more prolonged and downslurred "tsirrrrrrr"; calls are very similar to those of both *P. cinerascens* and *P. afer*. Song a typical parid series of whistled phrases, "toowee-toowee, toowee-teeyoo, toowee-teeyoo", "tsi-ttreeooo-tweetoo" or "twee-too-you, twee-too-you", repeated several times and often with introductory "trit".

**Habitat.** Almost entirely restricted to open and well-developed miombo (*Brachystegia*) woodland; occasionally in mavunda forest, and *Uapaca* and *Isoberlinia* woodlands. At 1220–1900 m in DR Congo, from 915 m (possibly as low as 400 m) to 1700 m in Malawi, and at 975–1950 m in Zambia; in Zimbabwe, above 915 m on C plateau and at 500–1600 m in E highlands.

**Food and Feeding.** Diet rather poorly known; presumably includes small invertebrates and larvae. Usually forages in pairs or in small (possibly family) groups; often joins mixed-species foraging flocks, including those with *P. cinerascens* where ranges overlap. Forages mostly in upper level and canopy, among the bark and branches (including largest limbs) of living and dead trees. Co-exists with *P. rufiventris* in mature miombo woodland, although the two species apparently occupy different niches.

**Breeding.** Season Aug–Dec. Nest a large, soft pad or cup of plant fibres, animal hair and feathers, placed in hole in tree, including old hole of woodpecker (Picidae) or barbet (Capitonidae), or in wall or fence post, or in termite hill, or in hole in ground or sloping bank, sometimes in drainpipe. Clutch 3–5 eggs, no information on incubation and nestling periods. Occasional brood host to Lesser Honeyguide (*Indicator minor*). Breeding success: 75% of nests in miombo woodland in Zimbabwe each fledged two young.

**Movements.** Resident.

**Status and Conservation.** Not globally threatened. Common or locally common in much of range. In Tanzania local and sparsely distributed, and fairly common only around Mt Rungwe. Densities of 14 individuals/100 ha of miombo woodland in Zambia. Considered potentially vulnerable owing to its specific habitat requirements; appears to be replaced by *P. cinerascens* in areas where habitat destroyed and substituted by secondary scrub and thornbush.

**Bibliography.** Alerstam & Ulfstrand (1977), Britton (1980), Clancey (1996a, 1996b), Dowsett-Lemaire & Dowsett (2006), Fry *et al.* (2000), Ginn *et al.* (1989), Hall & Moreau (1970), Harrop & Quinn (1996), Harrison *et al.* (1997), Hockey *et al.* (2005), Irwin (1959, 1981), Mackworth-Præd & Grant (1963, 1973), Maclean (1993), Short *et al.* (1990), Sinclair & Ryan (2003), Sinclair *et al.* (2002), Stevenson & Fanshawe (2002).

41. Ashy Tit

*Parus cinerascens*

**French:** Mésange cendrée      **German:** Akazienmeise      **Spanish:** Carbonero Cinéreo

**Taxonomy.** *Parus cinerascens* Vieillot, 1818, Pelladri, northern Cape Province, South Africa. Forms a superspecies with *P. thruppi*, *P. griseiventris* and *P. afer*. Has been considered conspecific with any one of those or with all of them. Birds from SE Zimbabwe and N South Africa (E Limpopo S to Free State), previously separated as race *orphnus* on basis of purer white face and nuchal patch and greyer upperparts, now considered doubtfully distinct from fresh-plumage nominate. Two subspecies recognized.

**Subspecies and Distribution.**

*P. c. benguelae* B. P. Hall & Traylor, 1959 – SW Angola, possibly also extreme NW Namibia. *P. c. cinerascens* Vieillot, 1818 – Namibia, Botswana, Zimbabwe and N South Africa (S to N Northern Cape, Free State and Mpumalanga).

**Descriptive notes.** 14.5–15 cm; 18.5–21.7 g. Large, grey tit with black-and-white head pattern and black breast. Male nominate race has forehead to crown and crown side (to below eye) and nape black, in fresh plumage slightly glossed bluish, white patch on centre of lower nape; upperparts grey, longest uppertail-coverts tipped blackish; tail black, all feathers (occasionally except central pair) tipped white, outermost narrowly edged white; upwerving-coverts blackish-grey, lesser coverts tipped as upperparts, medians and greater fringed and more broadly tipped buffish-white, alula and primary coverts black, finely fringed and tipped whitish; flight-feathers blackish-grey, tertials fringed greyish-white, secondaries as tertials but slightly duller on edges and whiter at tips, primaries finely fringed whitish; cheek, ear-coverts and neck side white; chin and throat to below ear-coverts and centre of upper breast black, slightly glossed blue on throat and breast, narrow black line from lower bib to belly bordered by narrow whitish to light greyish-buff; rest of underparts grey, except for darker undertail-coverts with whitish tips; axillaries and underwing-coverts greyish, tipped off-white; in worn plumage, crown and nape duller and less glossy, upperparts duller grey or washed brownish, less white at tips of tail, fringes of wing feathers abraded or absent, black may extend across side of neck to nape, bib duller, rest of underparts browner; iris brown to deep brown; bill black; legs blue-grey or dark grey to black. Distinguished from *P. griseiventris* by larger bill, brighter or more glossy cap, darker grey upperparts, darker underparts; from *P. afer* by grey upperparts and flanks, white (not buffish) nuchal patch, white (not pale brownish) wing edgings. Female resembles male, but is slightly browner on upperparts, including wings and tail, and bib is generally duller and less glossy. Juvenile is similar to adult, but crown to nape is sooty brown, upperparts tinged duller brown, tail darker brown with very narrow off-white tips, wings dark sooty brown, median and greater coverts have broad pale grey or buffish tips, edges of greater coverts narrower than on adult, bib browner, tinged dark grey and restricted to throat and breast, ventral line usually absent. Race *benguelae* differs from nominate in having underparts much paler, and lacking pale border between ventral line and flanks. Voice. Calls include a thin and fairly sibilant "si-si-si" or a longer and more complex series of "psi-psi" or "sisisi-si-si-si-si-si" notes, also a harsher "psi-psi-chrrr"; alarm a series of nasal rattles, dry chattering "jejejejejejeje" and prolonged "chrrrrr" or "tschrr tschrr tschrr". Song is a series of mellow trilling notes, "tlu-tlu-tlu-tlu-tlu-tlu, chi-chi-chi-chi-chi, tri-tri-tri-tri-tri", occasionally with slower variations, e.g. "trewet-treet-treet-treet-treetretretretretret". Voice very similar to that of *P. afer*.

**Habitat.** Mainly dry acacia (*Acacia*) savanna, particularly camel thorn (*Acacia erioloba*), and arid thornbush, scrub, edges of broadleaf (especially *Combretum*) woodland and riverine forest; also secondary scrub and light open deciduous woodland in South Africa (mainly W part of former Transvaal), and tall vegetation in very dry riverbeds and semi-desert country; usually avoids miombo (*Brachystegia*) woodland. Occurs at 275–1220 m in Namibia and 915–1370 m in South Africa;

mostly above 1200 m in Zimbabwe, but occasionally down to 900 m in S and to 1880 m in Inyanga highlands.

**Food and Feeding.** Diet includes small invertebrates, principally beetles (Coleoptera), moths (Lepidoptera), spiders (Araneae), ants (Hymenoptera), flies (Diptera) and larvae, also some fruit and seeds; nestlings fed mostly with lepidopteran caterpillars and pupae. Solitary, in pairs or in small groups; in non-breeding season often in mixed-species flocks, rarely including *P. griseiventris*. Forages in middle levels of trees and tall scrub, occasionally descends to ground; vigorously hammers at seedpods of camel thorn to extract invertebrate larvae.

**Breeding.** Season Sept–Apr. Monogamous; possibly a co-operative breeder, several adults attending breeding female and young at some sites. Territorial; male defends territory by vigorously singing from tall bush throughout incubation and nestling stages. Nest a cup of soft plant material, including down, animal hair and feathers, placed 2–4 m from ground in hole in tree trunk or old stump, or in hole in ground. Clutch 4–6 eggs; incubation by female, fed on nest by male, period 11–13 days; nestling period up to 22 days. Breeding success highly dependent on local rainfall; of 24 nests in Namibia, 12 failed prior to hatching owing to hot and dry weather, and remainder fledged at least one young each.

**Movements.** Resident, but locally nomadic. May wander in non-breeding season into areas of brachystegia woodland; in South Africa an irregular winter visitor to KwaZulu-Natal and possibly elsewhere in E & SE.

**Status and Conservation.** Not globally threatened. Common to fairly common or locally common. Density of 1 pair/50 ha of acacia thornveld in N South Africa.

**Bibliography.** Clancey (1958, 1996a), Dowsett & Dowsett-Lemaire (1993), Fry *et al.* (2000), Ginn *et al.* (1989), Hall & Moreau (1970), Hall & Traylor (1959), Harrop & Quinn (1996), Harrison *et al.* (1997), Hockey *et al.* (2005), Irwin (1981), Mackworth-Præd & Grant (1963), Maclean (1993), McCarthy (2006), Newman (1989), Penry (1994), Sinclair & Ryan (2003), Sinclair *et al.* (2002), Stevenson & Fanshawe (2002), Wiggins (2001).

42. Grey Tit

*Parus afer*

**French:** Mésange petit-deuil      **German:** Kapmeise      **Spanish:** Carbonero Gris  
**Other common names:** Southern Grey Tit, Acacia (Grey) Tit, African Grey Tit

**Taxonomy.** *Parus afer* J. F. Gmelin, 1789, Cape of Good Hope, South Africa. Forms a superspecies with *P. thruppi*, *P. griseiventris* *P. cinerascens*. Has been considered conspecific with any one or all of those. Two subspecies recognized.

**Subspecies and Distribution.**

*P. a. afer* J. F. Gmelin, 1789 – W South Africa (Northern Cape, Western Cape) and apparently also E, C & S Namibia. *P. a. arens* Clancey, 1963 – Lesotho and S South Africa (S Free State, W Eastern Cape).

**Descriptive notes.** 14–15 cm; 17.3–22.4 g. Medium-sized to large, dark grey tit with black head to breast and white lower face. Male nominate race has forehead to crown (to below eye) and nape black, in fresh plumage slightly glossed bluish; buffish or greyish-white nuchal patch; upperparts grey or dull brownish-grey, longest uppertail-coverts tipped blackish; tail sooty black, all feathers tipped dull whitish (may be reduced to small spot on central pair), outermost also narrowly edged whitish; upwerving-coverts dark grey-brown, lesser coverts tipped as upperparts, medians and greater fringed and more broadly

tipped off-white or buffish, alula and primary coverts black, finely fringed greyish; flight-feathers blackish-grey, tertials fringed dull greyish-white, secondaries and primaries finely fringed dull greyish-white; cheek, ear-coverts and neck side off-white; chin and throat to below ear-coverts and broad centre of upper breast black, slightly glossy blue on throat and breast, tapering into a narrow black line down to vent; sides of breast and belly white, washed pinkish, flanks pale buff or pinkish-buff, undertail-coverts darker with paler tips; axillaries and underwing-coverts blackish, tipped buffish to greyish-white; in worn plumage, crown and nape darker, less glossy, upperparts darker and washed brownish (less grey), white tips of tail abraded or absent, fringes of wing feathers abraded or absent (but tips to greater coverts may be bleached whiter), bib duller brown, rest of underparts more buffish; iris dark brown to black; bill black; legs grey, blue-grey or black. Distinguished from *P. cinerascens* and *P. griseiventris* mainly by shorter tail, buffish or greyish nuchal patch, duller upperparts and wing edgings, buff on underparts. Female resembles male, but slightly browner on crown, bib smaller and duller and usually more rounded (less pointed) on lower edge, and ventral line narrower. Juvenile is as female, but crown to nape browner, upperparts tinged duller brown, tail darker brown with narrower off-white tips (except outermost feather, which more broadly fringed and tipped off-white), bib browner; first-year separable from adult by contrast between fresh greater coverts and tertials and old primary coverts, primaries and secondaries. Race *arens* differs from nominate in having mantle, back and rump darker, deep greyish-olive, underparts slightly duller, more heavily buff-brown on sides of breast and belly, ventral stripe broader on upper belly, and flanks to vent duller and greyer, washed dull buff. Voice. Calls include series of thin and fairly sibilant "tsi-cha-cha-cha" or "tsisisi-cha-cha-cha-cha", and very similar to some calls of *P. cinerascens*; alarm a harsh "tchiptchre-tchre-tchre-tchre-tchre-tchre-tchre...", slightly softer than that given by *P. niger*. Song a series of repeated loud phrases, e.g. "we-toolee-too, we-toolee-too", "klee-klee-klee, chere-cheree, pee-peeoo, pee-peeoo pee-peeoo, piet-jou-jou" or "piet-jou-jou, tui-tui-tui", rather like notes of a *Turdus* thrush.

**Habitat.** Dry thorn-scrub, including arid Karoo areas of semi-desert, scrubby or bushy patches and fynbos, in open rocky country with gorges, including dry rivercourses and edges of agricultural areas; appears to favour lower-growth areas of vegetation, rather than trees; in S of range occurs principally in open *Tarchonanthus*/*Acacia* scrub. At 1220–1320 m in Namibia, 400–945 m in W South Africa (Northern Cape), and to 2745 m in Lesotho.

**Food and Feeding.** Diet includes small invertebrates, particularly wasps (Hymenoptera), ants (Formicidae), beetles (Coleoptera), spiders (Araneae) and larvae, especially moth caterpillars (Lepidoptera) up to 4 cm long; also fruit of honey-thorns (*Lycium*). Usually in pairs or in small, probably family, groups of up to six individuals; also in mixed-species foraging flocks containing crombecs (*Sylvietta*), Black-chested Prinia (*Prinia flavicans*), Rufous-eared Warbler (*Malcorus pectoralis*) and Cape Penduline-tit (*Anthoscopus minutus*). Active and restless. Forages in foliage of bushes, scrub and low shrubby trees; appears to locate prey items also from within bark on lower trunks and branches of taller trees. Hangs upside-down to locate and open items on undersides of branches; pecks or hammers at food items held in foot. Also opens up holes in thorns and acacia seedpods,

especially those of camel thorn (*Acacia erioloba*), by repeated pecking in order to extract insect larvae.

**Breeding.** Season Aug–Mar. Possibly a co-operative breeder. Nest built by both sexes, a thick pad or cup of grass, plant fibres, animal hair, wool and feathers, placed in hole or cavity in rocks, culvert or bank, or in drainpipe, fence post or old building, occasionally in tree if available in habitat. Clutch 2–5 eggs; incubation period up to 14 days; chicks fed by up to four adults at some nests, no information on duration of nestling period.

**Movements.** Resident or locally nomadic.

**Status and Conservation.** Not globally threatened. Uncommon or scarce. Fairly common in South Africa around Cape Town. Apparently present in Kwazulu-Natal (E South Africa) prior to 1970, but no recent records from there. Status of population in Namibia questioned; possibly requires confirmation.

**Bibliography.** Clancey (1996a), Dowsett & Dowsett-Lemaire (1993), Fry *et al.* (2000), Gill *et al.* (2005), Ginn *et al.* (1989), Hall & Moreau (1970), Harrap & Quinn (1996), Harrison *et al.* (1997), Hockey *et al.* (2005), Irwin (1959), Mackworth-Praed & Grant (1963), Maclean (1993), McCarthy (2006), Sinclair & Ryan (2003), Sinclair *et al.* (2002), Stevenson & Fanshawe (2002).

## 43. Great Tit

*Parus major*

**French:** Mésange charbonnière    **German:** Kohlmeise    **Spanish:** Carbonero Común  
**Other common names:** Grey Tit(!); Cinereous Tit ("cinereus group"); Japanese Tit (*minor*)

**Taxonomy:** *Parus major* Linnaeus, 1758, Europe.

Part of a species group which includes also *P. bokharensis*, *P. monticolus* and *P. nuchalis*. Forms a superspecies with *P. bokharensis*; has been treated as conspecific, but the two interbreed only rarely and locally, and genetic evidence indicates that they are better considered separate species. Hybridizes, very rarely, also with *Periparus ater* and *Cyanistes caeruleus*, and possibly with *Poecile palustris*. Geographical variation highly complex, and to some extent clinal, but three groups of races, or "sections", traditionally recognized: "nominate section", in Palearctic (except far E), containing the green-backed, yellow-bellied races (the first 12 of those listed below); "cinereus section", from SW Asia and Indian Subcontinent E to Indochina and Indonesia, containing the grey-backed, whitish-bellied forms (the next 13 in list); and "minor section", from E Asia and Japanese islands, incorporating the greenish-backed, white-bellied races (the final 9 in list). Recent analyses, using DNA evidence and hybridization studies, suggest that these sections should perhaps be treated as three separate species, largely isolated from one another by major landforms (e.g. Himalayas); also some differences in voice and habitat. On the other hand, a degree of intergradation and/or hybridization is evident in areas where groups meet, e.g. intergrades between *blanfordi* and *intermedius* and between *kapustini* and *minor* occur; further, race *karelini* thought by some to represent intermediate population between the first two of those, and is often included within nominate, and, moreover, *intermedius* and *commixtus* are themselves sometimes considered to represent merely intergrade populations. Some intergradation also within sections (e.g. between nominate and *aphrodite* in S Europe). Otherwise, within "minor group", birds from S China (SW Sichuan S to SE Xizang, Yunnan and W Guizhou) currently included within race *tibetanus*, but sometimes separated as *subtibetanus*, and *kagoshimae* merged with *minor* by some authors. Thirty-four subspecies presently recognized.

**Subspecies and Distribution.**

- P. m. newtoni* Prazák, 1894 – British Is, Netherlands, Belgium and NW France.  
*P. m. major* Linnaeus, 1758 – mainland Europe (Scandinavia S to N & C Spain, C Italy and Balkans), W & SC Siberia (E to L Baikal, S to N & E Kazakhstan and Altai), Asia Minor, Caucasus and Azerbaijan (except SE).  
*P. m. kapustini* Portenko, 1954 – SE Kazakhstan (Dzungarian Alatau), extreme NW China (NW Xinjiang) and NW Mongolia E to Transbaikalia, SE Russia (N Amurland) and Sea of Okhotsk.  
*P. m. corsus* O. Kleinschmidt, 1903 – Portugal, S Spain and Corsica.  
*P. m. mallorcae* Jordans, 1913 – Balearic Is.  
*P. m. excelsus* Buvry, 1857 – NW Africa (Morocco E to N Tunisia).  
*P. m. ecki* Jordans, 1970 – Sardinia.  
*P. m. aphrodite* Madarász, 1901 – S Italy, S Greece, Aegean Is and Cyprus.  
*P. m. niethammeri* Jordans, 1970 – Crete.  
*P. m. terraesanctae* E. J. O. Hartert, 1910 – Lebanon, Syria, Israel, Jordan and NE Egypt.  
*P. m. karelini* Zarudny, 1910 – SE Azerbaijan and NW Pakistan.  
*P. m. blanfordi* Prazák, 1894 – N Iraq and NC & SW Iran.  
*P. m. intermedius* Zarudny, 1890 – NE Iran and SW Turkmenistan.  
*P. m. decolorans* Koelz, 1939 – NE Afghanistan and NW Pakistan.  
*P. m. ziaratensis* Whistler, 1929 – C & S Afghanistan and W Pakistan.  
*P. m. caschmirensis* E. J. O. Hartert, 1905 – NW Himalayas E from N Pakistan.  
*P. m. nipalensis* Hodgson, 1837 – N India and Nepal E to W & C Myanmar.

**Descriptive notes.** 12.5–14 cm; 11.9–22.1 g. Large, black-headed tit with large white face patch, and pale or yellow underparts divided by black ventral line. Male nominate race has forehead to crown (to below eye) and nape glossy bluish-black, dull whitish patch on centre of lower nape becoming greenish-yellow on lowermost hindneck and upper mantle; rest of mantle, scapulars and upper back green, scapulars tinged olive, lower back to uppertail-coverts light bluish-grey, tinged green on rump, longest uppertail-coverts and tail bluish-grey with blackish inner webs, outer three rectrices tipped white (minutely on innermost of the

three), on outermost rectrix white extends as a wedge to about half feather length on inner web and over entire outer web; lesser and median upperwing-coverts greyish-blue, greater with blackish on inner webs and fringed finely greenish on outer and broadly tipped white, alula and primary coverts black, finely fringed white; flight-feathers blackish-grey, tertials broadly fringed pale green-

ish-yellow (becoming white towards tip), secondaries and inner primaries finely fringed pale greyish-blue; cheek and ear-coverts white, chin, throat and neck side to centre of upper breast black (slight blue gloss on throat and breast), fairly broad but irregular black line from lower bib to vent; sides of breast and belly bright lemon-yellow, flanks washed grey-green, undertail-coverts white with tips of longest blackish; axillaries and underwing-coverts whitish; in worn plumage, crown and nape duller, less glossy, upperparts duller green, ventral line slightly broader, rest of underparts paler yellow, or greyer on flanks; iris dark reddish-brown to blackish-brown; bill black, paler cutting edges; legs slate-grey to blue-grey. Differs from *P. bokharensis* mainly in slightly smaller white cheek patch, blue-grey fringes to flight-feathers, slightly larger size and larger bill, shorter tail; some races with greener (less grey) upperparts, bright yellow (not whitish) on underparts. Female like male, but slightly duller black on crown, upperparts duller or darker green, fringes of greater coverts and secondaries greenish-grey (not greyish-blue), black on side of neck narrower or broken, bib duller black, ventral line narrower and less intensely black (may be broken or show white tips towards vent), undertail-coverts more extensively white. Juvenile is as female, but crown to nape browner or brownish-olive, nuchal spot small and dingy, upperparts dull olive-green, greyer on rump and uppertail-coverts, tail duller and greyer with poorly defined whitish tips on outer two feathers, wing-coverts washed or fringed olive, flight-feathers dark grey, fringed grey-green on secondaries and pale grey on primaries; cheeks, ear-coverts and neck side pale yellow (whiter when worn), small dark grey bib in breast centre and trace of narrow dark grey ventral line, rest of underparts pale yellow, greyish wash on flanks; iris paler or greyer. Races fairly well defined, differing mainly in size, bill shape, intensity of yellow in plumage, and extent of white in outer tail: *newtoni* is as nominate, but bill slightly longer (and culmen less curved), mantle slightly deeper green, less white in outer tail, male with ventral line broadly black and widening on belly, female with black areas duller, ventral line also narrower and can be broken on lower belly; *kapustini* is paler above and below than nominate; *corsus* is as nominate, but upperparts slightly duller or darker, greyish-olive, has less yellow on nape and less white in tail, and underparts paler yellow except for greyish wash on flanks; *mallorcae* differs from nominate in slightly larger bill, more greyish-blue upperparts, slightly paler (pale yellow to greyish-white) underparts, less white in tail; *ecki* resembles last, but with bluish tinge on upperparts and slightly paler underparts; *excelsus* is as nominate, but brighter olive-green above, very little or no white on outer tail feather, underparts bright yellow (deeper than in previous two); *aphrodite* has upperparts slightly darker than nominate, more olive-grey, and underparts variably yellow to pale cream; *niethammeri* is very similar to last but with slightly larger bill, upperparts slightly duller or darker, less green, and underparts very pale yellow; *terraesanctae* is as previous two, but upperparts slightly paler; *blanfordi* is as nominate, but mantle and scapulars duller or greyer, underparts pale yellow (but darker in E & S Elburz Mts and into N Iraq), and more white in outer tail feather; *karelini* very similar to last or intermediate between it and nominate, but with less white in tail; *caschmirensis* has upperparts bluish-grey (darker than *ziaratensis*), tail blackish-grey and broadly fringed bluish-grey, outer rectrix entirely white and adjacent one white except on edge of inner web, tertials broadly fringed pale grey, flight-feathers narrowly edged same, underparts off-white or tinged buffish, slightly whiter on breast side and border of ventral line; *intermedius* is similar to last, but upperparts light bluish-grey (may be faintly tinged greenish), upper mantle tinged olive, greater coverts edged pale bluish-grey, alula black, much less white in tail, underparts creamy to pale greyish-white; *ziaratensis* is also similar but with slightly smaller bill, paler upperparts, broader and whiter edges of tertials, underparts whiter; *decolorans* has underparts darker and flanks greyer; *nipalensis* is also like *caschmirensis*, but upperparts slightly darker grey, tinged bluish, less white in tail (but outermost feather white), tips of greater coverts narrower and whiter, fringes of tertials whiter, underparts whiter; *vauriei* resembles previous, but flanks slightly greyer, white in outer tail restricted to distal half of outermost rectrix; *stupae* is similar to *caschmirensis*, but slightly darker bluish-grey above, greater coverts narrowly fringed bluish-grey, tertials whiter, outer tail feather white and adjacent one extensively so, underparts paler or tinged pale pinkish-buff (usually heaviest on female) except for pale grey flanks; *maharattarum* is closest to previous, but upperparts slightly darker or more heavily bluish-grey, less white in tail (outermost feather all white, but next one only half white), underparts duller smoky grey; *templeorum* is very like *nipalensis*, differs chiefly in having more black on greater wing-coverts; *hainanus* is similar to *caschmirensis* but slightly darker above, mantle often washed olive, greater coverts mostly black (narrowly fringed bluish-grey and tipped white), tertials fringed white, outermost rectrix white and distal half of inner web of adjacent one white, underparts pale greyish-white or dull cream, flanks greyer; *ambiguus* is also similar but smaller, with slightly darker upperparts, smaller nuchal patch, greater coverts black with thin bluish fringes, tertials fringed pale grey, white in tail reduced to most of outermost feather and tip of next, underparts slightly darker; *cinereus* is similar to previous, but upperparts slightly darker blue-grey, underparts paler and tinged pinkish, outer tail feather white and tips of next two also white; *sarawacensis* resembles last, but white nuchal patch reduced or absent, upperparts slightly darker grey, uppertail-coverts black, tail feathers also black with narrow grey fringes and white restricted to outermost rectrix (which has base of inner web black), underparts pale greyish-white, blackish ventral stripe broad; *minor* is similar to nominate, but uppermost mantle olive-yellow, becoming plain olive below and greyish-olive on scapulars and back, underparts mostly whitish, breast side and upper flanks washed pinkish-buff, lower flanks greyish, female also as nominate but with olive fringes of tertials; *dageletensis* is as previous but has less olive-green on mantle, underparts whiter, dark ventral line narrower; *kagoshimae* is similar but with darker flanks; *amamiensis* has olive-green only on upper mantle, contrasting with greyer lower mantle, back and rump; *okinawae* is as previous but less green (merely washed green on upper mantle), lower mantle to back and rump darker bluish-grey; *nigriloris* is similar to last but darker, lacks nuchal patch, green on mantle replaced by bluish-black (slightly glossy), becoming dark bluish-grey on rest of upperparts, tail mostly blackish-grey (white restricted to tip of outermost feather), lores and neck side broadly black and merging with bluish-black of bib (white on cheeks and ear-coverts reduced), underparts darker, with narrow whitish-grey border to lower bib and ventral line; *tibetanus* is similar to *minor* but larger, has dull olive or greenish-olive upperparts (much duller grey in worn plumage), more white in outer two tail feathers; *nubicolus* resembles last, but upper mantle slightly more yellow; *commixtus* is similar to *minor*, but generally less olive-green on mantle, greyer lower mantle and scapulars, variable amounts of white in outer two rectrices, and underparts slightly darker (tinged pinkish in fresh plumage).

**VOICE.** Male particularly vocal throughout year, with large repertoire and variety of calls, up to 40 distinct notes recorded. Single call notes include soft "pit", "spick", "chit" or "squink", often as contact when foraging and as introductory notes to longer series of other calls, a loud metallic "tink" or "chink" used almost exclusively by adult male in variety of situations e.g. alarm, territory defence (often during prolonged "tinkling duels" with rivals at territory boundaries), aggression and during winter flocking, and very similar to one of the calls given by Common Chaffinch (*Fringilla coelebs*), similarity further enhanced when repeated as rapid double or treble "tink-tink-

tink", also often as precursor to full song; may be given also by female in territory defence close to nest-site, often with thin or sharp "tsee". Churring "chich-ich-ich-ich" or "chach-ach-ach" (similar to that of *Cyanistes caeruleus* but louder), often preceded with single "tsee", "tink" or "pee-tink", may be given lightly as contact between partners, also during courtship, and more prolonged, emphatic and harshly when alarmed or agitated; also a dry, rising "chur-r-r-rihihi", often as prelude to heavy scolding churr. Other calls include dry, nasal "tcha-tcha-tcha" (variation of churring call) and reminiscent of similar phrase of *Poecile palustris*, rather explosive "chack-chack-chee..." and "spick-spick-pee-peu-peu", and variety of similar notes, including "tsee-tsui" in anxiety and aggression; during courtship and display male gives low warbling "ziddle zeeeeeeee" or "tri li li deeeee", female responding with similar but lower "zeedle-zeedle-zeedle" (occasionally as more rapid "zzrrree zrrree..."); female on nest may give loud, explosive hissing note, possibly as defence against potential predator. Fledglings have loud, high-pitched "tsee-tsee-tsee-tsee-tsee" or more emphatic "zicker-zicker-zicker", and shorter "zi-zi-zi" contact note. Song almost entirely uniform across range (but in playback experiments captive female *cinereus* showed no reaction to song of nominate, although song of *cinereus* elicited full territorial response when played to *minor* from SE Russia); male territorial song usually a loud, sharp and slightly metallic "tea-cher, tea-cher", "teecheewee teecheewee", "tsi-tsi-daa tsi-tsi-daa" or "zizibaah zizibaah", usually repeated several times (exceptionally, up to ten times); only slight geographical variation, e.g. throughout Indian Subcontinent, Malay Peninsula and Indonesia ("cinereus group") song "chew-a-ti, chew-a-ti, chew-a-ti", "sweet-pepe-ti, sweet-pepe-ti" or "weeter-weeter-weeter" and the like; also usual for males to have at least three songs of differing tempo. Song of female very similar to that of male but rarely given. Both sexes give soft subsong (normally from within foliage, almost inaudible except at close range) of random warbled notes, usually from end of winter to start of nest-building or fledging of young.

**Habitat.** Mostly open deciduous and mixed forests and edges and clearings in dense forest, including conifer forests and boreal taiga of N Siberia; also more widely in plantations, hedgerows, orchards, parks, gardens (including in urban and suburban areas), edges of cultivation, olive groves and almost any group of trees or bushes. In Europe shows preference for oaks (*Quercus*); in Siberia, W China and Mongolia principally in riverine birch (*Betula*) or willow (*Salix*) thickets and mixed forest, and in isolated clumps of trees on otherwise open steppe, around villages and other settlements, in Mongolia also in open semi-desert and montane forest. In SW Jordan a small population exists in scattered junipers (*Juniperus*) and oleanders (*Nerium*) at edges of wadis; in NW Africa favours cork oak (*Quercus suber*) and holm oak (*Quercus ilex*) and Atlas cedars (*Cedrus atlantica*), and occurs in palm groves in S Morocco. In W Pakistan (Baluchistan) breeds in juniper and pine (*Pinus*) forest, but in Himalayas mostly in deciduous and mixed forest, preferably open forest of oak, but also horse chestnut (*Aesculus*), pine and deodar (*Cedrus deodora*) and, E of N Pakistan, sal (*Shorea*) forest and acacia (*Acacia*) groves, and at higher levels in orchards, poplars (*Populus*) and willows; in peninsular India, W Myanmar and N Thailand found mainly in dry deciduous forest, groves or scattered trees in open and hilly country, but rarely in evergreen forest (except in NW Thailand, where evidently prefers stands of pines in evergreen forest); in non-breeding season in wider variety of habitats, including roadside and riverine trees and scrub-forest. In N Laos occurs in pine woods and in deciduous dipterocarp in S; in Malay Peninsula and Borneo only in coastal and riverine forest, nipa palms, *Casuarina* stands and mangroves. In Greater and Lesser Sundas found in wide variety of deciduous, coniferous and secondary forests, including montane heath and grasslands above tree-line. In Europe principally in lowlands (rare above 500 m in Scotland), but to 1950 m in Switzerland; in Middle East to 1800 m in Lebanon, and in NW Africa to 1850 m; in NE Afghanistan 1000–2600 m, and in Himalayas mostly to 1800 m but 1200–2440 m in NW India (and to 3660 m in Chitral and Ladakh), and exceptionally to 3050 m in summer in Nepal, generally lower in E Himalayas (but to c. 1500 m in Arunachal Pradesh); in peninsular India at 610–915 m in Eastern Ghats and 120–2285 m in Kerala, and in Sri Lanka mostly 600–1770 m (or lower locally); in C China 300–1650 m (most towards upper limit, owing to persecution and lack of lowland habitat), but in S up to 4040 m in Xizang and 4420 m in Sichuan; at 500–1100 m in W Myanmar (Mt Victoria) and 800–2135 m in NW Thailand, and to 2000 m in Sumatra and Java; in Lesser Sundas, from sea-level to 930 m on Sumba, to above 1000 m on Sumbawa, 1400 m on Flores and 2400 m on Lombok; in Japan occurs to 1800 m, exceptionally to 2200 m.

**Food and Feeding.** Well studied. Food in summer mostly small invertebrates and larvae (usually up to 1 cm); at other seasons also seeds and various other items. Invertebrates include cockroaches (Blattodea), grasshoppers and crickets (Orthoptera), damselflies and small dragonflies (Odonata), lacewings (Neuroptera), earwigs (Dermaptera), bugs (Hemiptera) including aphids (Aphidoidea), ants (Formicidae), millipedes (Diplopoda), mites (Acari), moths (Lepidoptera), flies (Diptera), caddis flies (Trichoptera), scorpion flies (Mecoptera), bees (from which stings usually removed) and wasps (Hymenoptera), beetles (Coleoptera), spiders (Araneae), harvestmen (Opiliones), snails (Gastropoda), woodlice (Isopoda). Seeds and fruit (mostly in non-breeding season) mainly those of deciduous trees and shrubs, particularly seeds of beech (*Fagus sylvatica*) and hazel (*Corylus avellana*); also takes spilled grain (mostly wheat and maize) in fields, and takes fat, bread, cheese, household scraps (including meat), peanuts and sunflower seeds from birdtables (in severe winter weather estimated to consume 44% of its own weight in sunflower seeds); also takes nectar from fritillary (*Fritillaria*) and currant (*Ribes*) and sap from walnut (*Juglans*) and vines (*Vitis*). Nestlings fed mostly (not exclusively) with lepidopteran larvae, especially in deciduous woodland; in pine woods, spiders, beetles and sawfly larvae (Symphyta) form greater proportion of diet. In Britain and some other parts of Europe, shares with *Cyanistes caeruleus* the acquired habit of piercing milk-bottle tops on doorsteps to sip cream. Does not store food, but may steal from caches of tits that do (e.g. *Parus ater* and *Poecile palustris*); highly intelligent and quick to learn, especially from partner or from others in flock, where to find hidden food. Seeds, particularly hard-shelled ones and nuts, often collected and taken to branch, where held firmly by foot (or feet) and rapidly hammered with the bill until a hole is made through which the kernel can be extracted; some, particularly larger seeds, may be wedged in bark before being opened. Occurs singly or in pairs, also in groups, in autumn frequently in large groups consisting solely of juveniles, and in winter up to 50 together (including first-years and adults) as part of a mixed-species foraging flock. Within single-species flock males dominate, and hierarchy of males usually dependent on proximity of territory, with territory-owner usually most dominant; dominance in winter flock increases likelihood of surviving winter. Forages at all levels in trees, but usually avoids tallest canopy; most often in lower levels of trees, where it gleams among foliage, branches and trunks, also in shrubs and tall undergrowth. Also on ground, especially male in non-breeding season, where collects fallen seeds, berries and invertebrates. Occasionally hovers for very brief moments, but rarely pursues insects in flight; commonly hovers at garden feeders and birdtables. One of the few bird species known to use a tool in obtaining food items; recorded as holding a conifer needle in the bill and using it as a means of extracting larvae from hole in tree.

**Breeding.** Season mostly late Jan to Sept (lays from late Mar onwards in W Palearctic), in Israel also exceptionally Oct–Dec (following post-breeding moult), start of laying usually heavily influenced by amount of sunlight and daytime temperatures (or provision of extra food), also by altitude and by age of female; breeds throughout year in Java, with peak Apr–Jun; usually two broods (less

frequently in deciduous woodland), rarely at same site but can be up to 200 m apart, and three broods not unknown. Monogamous, rarely polygamous; pair-bond lasts for duration of breeding season, may re-form in autumn and in following season (if both partners still alive). Territorial, boundary usually established by late Jan, and enforced with aggressive behaviour (mostly towards trespassing first-year birds) from late winter and early spring, defence usually declines following completion of clutch but in some areas maintenance of territory may be central to successful breeding; in S of range (Israel) territorial throughout year, and does not form flocks; generally solitary breeder, but pairs sometimes nest very close to each other, e.g. simultaneously in nestboxes 3–4 m apart in same tree. Displaying male keeps slightly higher than female, perches horizontally or hops with wings slightly raised and opened, tail raised and partly spread, occasionally raises and lowers tail and shivers wings while giving warbling trill, both birds then flying with shallow wingbeats or gliding to area of hole and inspecting potential nest-site; male courtship-feeds female, which crouches on branch and shivers wings, begging by female increases at start of egg-laying, during start of incubation and just before young leave nest. Nest built by female, mostly of plant fibres, grasses, moss, animal hair, wool and feathers, placed at variable height in hole or cavity in tree, occasionally in wall, rock face or building, frequently in nestbox (often used in preference to natural hole; in some cases entire population dependent on availability of boxes), exceptionally in old squirrel (Sciuridae) drey, in disused nest of other bird or in dense tangled vegetation; sometimes (especially "cinereus group") in rodent burrow, and in E of range often in hole in bank or ground; territory size variable, 0.5 ha to c. 3.6 ha. Clutch generally 5–12 eggs, slightly fewer in second broods and in areas of poor habitat, occasionally more, up to 18; incubation by female, fed on nest by male, start often delayed for several days (exceptionally, a week) after clutch completed or may begin up to three days before completion, incubation period 12–15 days; chicks fed by both parents, daily intake of food by nestlings c. 6–7 g but varies with availability of food (less on cold and wet days), can survive and fledge on as little as 3.2 g per day, and first broods receive more than do second broods; nestling period 16–22 days; young become independent c. 8 days after fledging, but often fed by parents (especially male) for up to 25 days more, and those of second broods may be fed for up to 50 days. Breeding success variable and dependent on a wide range of factors, including age of adults, rate of predation, starvation, changes in temperature and prolonged cold or rain in summer; age of male affects number of fledged young, age of female affects laying date and clutch size; established pairs have larger clutches and higher success rate than those breeding for first time (even when one partner has bred previously). Number of young fledged (as proportion of eggs laid) variable between broods and habitats, in S England broadleaf woodland 95% (1st brood) and 59% (2nd brood); in W German larch wood 61% (1st brood) and 76% (2nd brood); in S France evergreen oak woodland 42% (1st brood, largely as a result of unexplained desertion) and 55% (2nd brood); birds breeding in conifer woodlands appear to do better, with S England pines 60–62% (1st brood) and 78–87% (2nd brood), and 97% of 1st broods in conifer woodland in Sweden. In S England study in deciduous woodland 23% of nests failed due to predation by weasels (*Mustela nivalis*) over 29-year period, with marked fluctuation from year to year depending on availability of alternative prey; other significant predators include grey squirrel (*Sciurus carolinensis*), Eurasian Sparrowhawk (*Accipiter nisus*), Great Spotted Woodpecker (*Dendrocopos major*), Eurasian Jay (*Garrulus glandarius*) and cats. Mortality rate of juveniles rather high, 71% of young die within 400 days of fledging, greatest cause of death starvation; juveniles from second broods particularly vulnerable, have to compete with older, more dominant and frequently aggressive first-brood juveniles for food and foraging areas. Breeds within first year. Adult mortality fairly high, about half of breeding adults not reaching subsequent breeding season; ringing studies in England give annual survival rate c. 44% for males and c. 52% for females (mortality significantly lower in years of low population than in years when population high), and studies elsewhere in Europe show that adult mortality is comparable to that found in England, rising to 70% in St Petersburg (Russia), but mortality rate among first-years variable (from 61% in Czech Republic to 87% in Netherlands); mortality also increases for adults more than 5 years old, after which age females have lower reproductive rate and young have lower post-fledging survival rate. Maximum recorded longevity 15 years.

**Movements.** Resident, altitudinal migrant and partially eruptive. In C & S Europe largely sedentary, but also eruptive in autumns when population high (and often when beech crop poor and in conjunction with other factors). In late summer and autumn, dispersing flocks of juveniles (which can include some only c. 1 week out of nest) wander in random manner usually within a short distance of breeding range (second-brood young generally moving farther than those fledged earlier), but may gather in larger numbers at favourable feeding localities; by late autumn or early winter numbers within flocks usually reduced by c. 50% through death or emigration, and flock usually more settled in area that it will occupy throughout winter. Adults (especially males) remain on breeding territory throughout year if conditions permit (including in areas of NW Siberian taiga), but may join flocks for short periods in mid-winter, especially when flocks pass through territory (in late winter, males more likely to be within territory in preparation for breeding season). Evidence from ringing in British Is shows most movements within 10 km, and that 95% of females refound within 36 km of place of ringing and same number of males within 20 km, exceptions being mid-winter movements across North Sea to Netherlands and Lithuania. In eruption years, flocks usually totalling no more than 2000 individuals, mostly of first-year birds from N populations (where winter daylight too short to find food), move S & W in Sept and Oct to around Baltic region (30% of recoveries from Moscow region within 100 km SW of ringing site), Netherlands, Britain and Ireland; some travel farther, 1700–2700 km, to as far S as the Balkans, upper reaches of R Danube, Switzerland and NE Italy; included in such movements are birds from Russia recovered in Germany, Netherlands and Britain, and in extreme cases individuals from Kaliningrad (W Russia) reaching S Ireland and SW France. In NW Russia in vicinity of large cities, most first-years and adults are resident; mostly resident also in Latvia, but in Lithuania more migratory, with recoveries in S France and Portugal; similarly, many first-years from W Siberia recovered S of breeding range in Kazakhstan. Return movements to breeding areas in Feb–Mar, but in eruption or invasion years individuals may remain to breed in areas occupied during the winter (spread of range into N Norway resulted from winter invasions). In Vladivostok region of SE Russia, some resident but majority depart from breeding areas in Sept–Oct and return Mar–Apr; in Japan, many in N (Hokkaido) move SW to Honshu after breeding. Many of those breeding at higher elevations in Asia, as e.g. in parts of Indian Subcontinent and China, descend to lower levels after breeding. Vagrants recorded in Iceland, Canary Is (Tenerife, Fuerteventura), Malta, Bering Straits (Little Diomedé I) and Taiwan.

**Status and Conservation.** Not globally threatened. Common, locally common or abundant; not uncommon in Morocco but scarce N Algeria, and rare Saharan Atlas; rare in S Bhutan. Status in Borneo requires clarification, species perhaps only locally common and confined to coastal and riverine forests and mangroves. In Lesser Sundas, moderately common or very common at sea-level and above 1000 m on Flores; also two old records on Timor, where status requires confirmation. Estimated European breeding population (excluding Russia) 40,000,000–60,000,000 pairs. Densities in S England (pairs/km<sup>2</sup>) 20–320 in mixed deciduous woods, 80–330 in oak woodland, 6–53 in pine plantation; in NE Poland (Białowieża forest), 24 pairs/km<sup>2</sup> in alder (*Alnus*) swamp-forest, 26 in mixed ash-alder (*Fraxinus-Alnus*) forest, 19–24 in mixed oak-hornbeam (*Quercus-*

*Carpinus* forest and 1–2 in mixed coniferous forest. During 20th century, range in Europe expanded N into Norway, Finland and N Scotland, also significant increases in Netherlands and Estonia, and by more than 50% in Ukraine, since 1970. In E Mediterranean, spread S in Israel between 1950 and 1970 with growth of human settlements; became established in N Sinai (NE Egypt) in early 1970s and now locally common there. Since 1978 has spread to S Kamchatka, where now resident around towns and adjacent areas of forest. Generally, a very familiar parid in much of its range, and one of the world's best-studied avian species.

## 44. Turkestan Tit

### *Parus bokharensis*

**French:** Mésange du Turkestan **German:** Turkestanmeise **Spanish:** Carbonero Turquestano

**Taxonomy.** *Parus bokharensis* M. H. C. Lichtenstein, 1823, Bukhara, south Uzbekistan. Part of a species group which includes also *P. major*, *P. monticolus* and *P. nuchalis*. Forms a superspecies with *P. major*; has been treated as conspecific, but the two interbreed only rarely and locally, and genetic evidence indicates that they are better considered separate species. Paler birds from oases in Transcasian deserts sometimes separated as race *panderi*. Three subspecies currently recognized.

#### Subspecies and Distribution.

*P. b. bokharensis* M. H. C. Lichtenstein, 1823 – SC Kazakhstan, Ukbekistan, Turkmenia and extreme NE Iran E to N Afghanistan.

*P. b. turkestanicus* Zarudny & Loudon, 1905 – SE Kazakhstan E to extreme NW China (N Xinjiang), possibly also extreme SW Mongolia.

*P. b. ferghanensis* Buturlin, 1912 – mountains in Tajikistan (Pamir, Alai) and Kyrgyzstan E to W Tien Shan.

**Descriptive notes.** 14.5–15 cm; 16.9–18 g. Large, grey tit with black-and-white face pattern, long tail slightly graduated (outer two feather pairs shorter than central pair). Male nominate race has forehead to crown and crown side (to below eye) and nape glossy bluish-black, large dull whitish nuchal patch; upperparts pale bluish-grey, paler and more sandy in deserts of Transcasia (*“panderi”*), longest uppertail-coverts tipped grey; tail grey with blackish inner webs, outer three rectrices tipped white, outermost almost entirely white (only edge of inner web black); lesser and median upwing-coverts dark grey, edged

pale grey, greater with blackish inner webs and fringed pale grey and broadly tipped white, alula and primary coverts pale grey, largest alula feather finely fringed white; flight-feathers blackish-grey, tertials broadly fringed pale greyish and tipped white, secondaries similar, primaries finely fringed pale greyish-blue; cheek and ear-coverts to nape side white, chin, throat and side of neck to centre of upper breast black, slightly glossed blue on throat and breast; narrow black line from lower bib to vent, rest of underparts creamy white, flanks washed grey, undertail-coverts white with longest tips dark grey; axillaries and underwing-coverts whitish; in worn plumage, crown and nape duller, less glossy, nuchal patch slightly larger, white tips of tail abraded or absent, fringes of wing feathers abraded or absent, bib slightly larger, ventral line slightly broader; iris dark brown; bill black; legs slate-grey. Differs from *P. major* mainly in much greyer appearance, paler underparts, slightly smaller size and smaller bill, longer tail. Female resembles male, but slightly duller black on crown, upperparts duller or tinged browner, bib duller and restricted to centre of upper breast, underparts duller white, dark ventral line narrower and less intensely black. Juvenile is as female, but crown to nape brownish-olive and lacking gloss, nuchal spot tinged yellowish, upperparts tinged olive-green, tips of greater coverts yellowish, cheeks and ear-coverts yellowish (whiter when worn), chin and throat blackish (colour not extending to side of neck), bib reduced to small dark spot in centre of breast, ventral line to only a trace of narrow dark grey down to belly centre, rest of underparts pale yellowish. Racial variation slight: *ferghanensis* differs from nominate in having slightly smaller bill, upperparts slightly paler greyish-blue, flanks washed darker grey, juvenile more visibly yellow on face and underparts; *turkestanicus* is as nominate, but bill slightly larger, upperparts darker (but paler than previous). **VOICE.** All vocalizations very similar to those of *P. major*. Calls include combinations of “pee” or “tink” in short series with other notes, e.g. churring “chrrrr-ich-ich-ich” and a “tchrrrrrrrr” like that of sparrow (*Passer*) as alarm, also with various trills, including mellow “whi-whi-whi-whi”, coarser but strident “chi-chi-chi-chi” and more rapidly delivered “pipipipi”. Song “pid-du, pid-du, pid-du”, rather similar in tone to song of *Periparus ater*, often thinner or more plaintive than that of *P. major*; also a ringing “pink-it, pink-it” and a descending “chee-chee-chee-chee”.

**Habitat.** Throughout much of range occurs in lowland plains and semi-desert areas, usually in riverine woodlands of willows (*Salix*), poplars (*Populus*), including turanga (*Populus euphratica*) groves, tamarisks (*Tamarix*) and saxaul (*Haloxylon*), often with well-developed layer of shrubby vegetation and similar scrub; also in semi-desert oases, orchards and edges of cultivation, parks and gardens. In upland areas occurs in more heavily wooded areas, including conifers, deciduous and mixed woodlands; also in open areas with scattered trees and bushes. To 1550 m in NE Afghanistan, 2000 m in Kazakhstan, and 2135 m in Tien Shan.

**Food and Feeding.** Diet poorly known, but considered to be very similar to that of *P. major*; in addition to small invertebrates and larvae, some seeds. Usually in pairs in breeding season; at other times forms small groups, or occasionally larger groups of up to 100 individuals. Sometimes shy or skulking. Forages at all levels of vegetation, mainly by gleaning.

**Breeding.** Poorly known. Season Apr to late Jun; occasionally two broods. Nest, mostly of animal fur and some plant fibres, placed in hole in tree, wall or side of a building, or in steep earth bank. No other information available.

#### Movements.

Resident.

**Status and Conservation.** Not globally threatened. Locally common; rare in NE Iran, and uncommon in NW China. Status in Mongolia uncertain; further fieldwork required.

**Bibliography.** Cheng Tsohsin (1987), Dementiev *et al.* (1954, 1970), Étiénope & Hùe (1983), Formozov *et al.* (1993), Harrap & Quinn (1996), Hartert (1905, 1921), Hollom *et al.* (1988), Hùe & Étiénope (1970), Johansen (1944), MacKinnon & Phillips (2000), McCarthy (2006), Meyer de Schauensee (1984), Porter *et al.* (1996), Rasmussen & Anderton (2005), Vaurie (1959).

## 45. Green-backed Tit

### *Parus monticolus*

**French:** Mésange montagnarde **German:** Bergkohlmeise **Spanish:** Carbonero Dorsiverde

**Taxonomy.** *Parus monticolus* Vigors, 1831, Simla, Himalayas, north India.

Part of a species group which includes also *P. major*, *P. bokharensis* and *P. nuchalis*. N nominate race and *yunnanensis* intergrade in W Nepal. Four subspecies recognized.

#### Subspecies and Distribution.

*P. m. monticolus* Vigors, 1831 – W & C Himalayas from N Pakistan F to W Nepal and SW China (S Xizang).

*P. m. yunnanensis* La Touche, 1922 – E Himalayas E to NE India (including S Assam), C & S China (S Gansu and S Shaanxi S to S Yunnan and Guizhou), W, N & NE Myanmar, extreme NW Vietnam and C Laos.

*P. m. legendrei* Delacour, 1927 – Langbian, in SC Vietnam.

*P. m. insperatus* Swinhoe, 1866 – Taiwan.

**Descriptive notes.** 12.5–13 cm; 12–16.8 g. Large, black-capped tit with broad black ventral line, greenish upperparts and double wingbar. Male nominate race has forehead to crown (to below eye) and nape glossy bluish, small whitish patch on centre of lower nape; upper edge of mantle yellowish, rest of mantle, and scapulars and upper back bright olive-green, rump light grey, uppertail-coverts blackish, tips of longest bluish-black; tail black, fringed dull violet-blue, all feathers tipped white, outermost rectrix with outer web entirely white and broad white wedge at tip of inner web; lesser upwing-coverts fringed

pale grey, median coverts blackish, finely fringed and tipped white, greater blackish, finely fringed bluish-grey and broadly tipped white, alula and primary coverts black, finely fringed white; flight-feathers sooty black, tertials fringed and broadly tipped white, secondaries and inner primaries finely fringed violet-blue; cheek and ear-coverts to nape side white; chin, throat and side of neck to centre of upper breast black, slightly glossed blue on throat and breast; fairly broad but irregular black line from lower bib to vent; rest of underparts bright lemon-yellow, flanks washed olive, undertail-coverts blackish, broadly tipped white; axillaries and underwing-coverts whitish; in worn plumage, crown and nape duller, less glossy, wing and tail feathers browner, and pale tips of greater coverts and fringes of tertials may be abraded or absent; iris light brown to dark brown; bill black, paler cutting edges of lower mandible; legs slate-grey to blue-grey. Differs from *P. major* mainly in having two wingbars (not one), somewhat brighter green upperparts, bluish edges of flight-feathers. Female is very like male, but has wing and tail browner, fringes of greater coverts, secondaries and primaries duller or greyer, bib duller, more sooty black, and ventral line narrower and less intensely black. Juvenile is as female, but crown to nape browner and lacking gloss, smaller and pale yellowish nuchal spot, upperparts slightly duller, tips of wing-coverts and edges of tertials yellowish, cheeks and ear-coverts pale yellow (whiter with wear), bib reduced to small patch to centre of breast and narrow dark brown ventral line to centre of belly, rest of underparts duller yellow, washed greyish-olive on flanks; juvenile female slightly paler or browner, with slightly deeper yellow wash on tips of greater coverts and tertial edges, and duller or greyer edges of flight-feathers. Racial variation mostly slight: *yunnanensis* is as nominate, but upperparts slightly deeper green, wingbars slightly broader, and underparts brighter yellow with narrower ventral stripe; *insperatus* resembles previous, but tertials fringed bluish, broad white spots at tips of median and greater coverts, and smaller white tips on secondaries; *legendrei* is similar to nominate, but upperparts duller, greyish olive-green, with grey rump, white tips of median coverts narrow and tips of greater slightly broader (less than on previous race), tertials fringed bluish (as previous), breast and belly mostly black (or a much wider ventral line), with yellow paler and restricted to breast side and flanks. **VOICE.** All calls, including range of variation, similar to those of *P. major*, but generally louder or more shrill, and include rapid “fit-schew” and thin “si-si-si-si-li”; flight and contact calls include 3-note “te-te-wheel”; also has a more musical “pling pling pling”, often terminating with “tee-urr”; alarm a 3-note harsh “shick-shick-shick”; in Taiwan (race *insperatus*) a distinctive, rapid and mechanical “heeb t-t-tk, heeb t-t-tk, heeb t-t-tk”, frequently repeated. Song, from early Feb to late May in Nepal and from mid-Apr in Pakistan, a repeated series of disyllabic notes, one note shorter than the other, a rising “seeta-seeta-seeta” recalling a similar phrase given by *Periparus ater*, also “teeye-teeye-teeye” or “tu-weeh, tu-weeh, whi-ee, whi-ee...”; variations include “whicky-whicky, ti-ti-tee-it, tsing-tsing-pi-du, psit-psit-tutu”, also a song of repeated notes on same pitch, “piu-piu-piu...” or “pli-pli-pli-pli”.

**Habitat.** Mainly temperate and subtropical forests, including deciduous forest, principally oak (*Quercus*) and alder (*Alnus*), mixed and coniferous stands, to moist subtropical evergreen forest and higher-altitude birch (*Betula*) and juniper (*Juniperus*); also in undergrowth of bamboo and scrub. In non-breeding season also in forest edge and more open areas of orchards, walnut (*Juglans*) groves, edges of cultivation and gardens. Breeds at 1600–2800 m in W Himalayas and 1200–3660 m in E Himalayas, and 915–2650 m in NE Myanmar; 1980–3650 m in SW China (Xizang) and 1100–3960 m in SC China (Sichuan and Yunnan), 220–500 m in C Laos and 915–1585 m in S Vietnam; 600–2800 m in Taiwan. In non-breeding season also at lower levels, down to 580 m in N Pakistan, to 800 m in foothills in Bhutan and to 315 m in N Myanmar; in SC China (Sichuan) winters at 100–3050 m.

**Food and Feeding.** Diet not well known, but includes small invertebrates and larvae, flower buds, some fruit, including berries, and seeds. Usually in pairs, but in post-breeding season more often in small family groups of up to 20 individuals; also frequently in mixed-species foraging flocks with small babblers (Timaliidae), warblers (Sylviidae) and flycatchers (Muscicapidae), occasionally with *P. major* in W & S China. Generally tame and confiding, in certain areas often enters houses in

villages. Forages actively and acrobatically at all levels in forest trees (though more often in canopy in deciduous trees) and in undergrowth; also searches trunk and branches of trees, and in non-breeding season frequently on the ground. Appears able to withstand deep snowfall and to find food during periods of severe winter weather.

**Breeding.** Season Feb–Jul, but in Taiwan possibly throughout year (most in Mar–Jun); one brood. Nest, built solely by female, a soft pad of grass, plant fibres, moss, animal hair, wool and feathers, placed usually below 3 m, exceptionally to c. 7 m from ground, in hole or cavity in tree trunk, old stump, or fence post, or in hole in rocks or earth bank, sometimes in nestbox or hole in wall, or under eaves of house. Clutch 4–8 eggs; incubation by female, fed on nest by male; chicks fed by both parents. No information on duration of incubation and nestling periods.

**Movements.** Largely resident or short-distance altitudinal migrant. Some spend winter months at very high levels (2680 m in Sikkim, 3900 m in Nepal), but others descend to lower levels of foothills and adjacent plains in Oct–Mar non-breeding season. In N Pakistan, moves lower into Salt Range and Murree Hills and S to Peshawar and Islamabad; in N India occurs in N Punjab and around Dehra Dun (Uttar Pradesh), and farther E makes post-breeding descent into foothills of Bhutan and in N Myanmar; also in China. Vagrant to Ladakh and Bangladesh.

**Status and Conservation.** Not globally threatened. Common or fairly common throughout range; locally abundant.

**Bibliography.** Ali & Ripley (1983), Bates & Lowther (1952), Cheng Tsohsin (1987), Échécopar & Hùe (1983), Fleming *et al.* (1979), Gill *et al.* (2005), Grimmett *et al.* (1998), Harrap & Quinn (1996), Hartert (1905), King *et al.* (1975), MacKinnon & Phillips (2000), Meyer de Schauensee (1984), Rasmussen & Anderson (2005), Roberts (1992), Robson (2000), Smythies (1986), Spierenburg (2005), Stuart Baker (1932), Vaurie (1959).

## 46. White-naped Tit

### *Parus nuchalis*

**French:** Mésange à ailes blanches **German:** Weißflügelmeise **Spanish:** Carbonero Nuquiblanco  
**Other common names:** White-winged Black Tit(I), Collared/Pied Tit

**Taxonomy.** *Parus nuchalis* Jerdon, 1845, Eastern Ghats, India.

Part of a species group which also includes *P. major*, *P. bokharensis* and *P. monticolus*. Monotypic.  
**Distribution.** NW & S peninsular India.

**Descriptive notes.** 12–13 cm; 13–14.5 g. Medium-sized, strongly patterned, pied tit. Male has forehead and upper lores to crown, nape and most of upperparts, including all wing-coverts, glossy bluish-black; large or prominent white patch on lower nape and upper mantle; central tail feathers black, narrowly tipped white, outer two pairs (and outer web and tip of next inner) white; flight-feathers black, but tertials largely white (only centres at base black), innermost secondary edged and tipped white, rest of secondaries broadly white at bases, white increasing in extent onto primaries, all secondaries and primaries tipped

white (narrowly on primaries); cheek, ear-coverts and side of neck white or creamy white; chin, throat (narrowly onto throat side) and breast black or glossy bluish-black, broad blackish ventral line extending to lower belly, rest of underparts creamy, or slightly whiter on lower flanks; axillaries and underwing-coverts whitish; iris dark brown; bill black; legs slate-grey. Female differs from male in having slightly duller and less glossy upperparts, nuchal patch smaller, less white on tertials and bases of flight-feathers and white tips restricted to inner feathers, with cheeks and ear-coverts duller, chin yellowish-white, bib and ventral line sooty brown, rest of underparts yellowish. Juvenile is similar to adult, but head and upperparts sooty black and lacking gloss, nuchal patch pale creamy yellow, white on outer tail feathers duller or washed brownish, usually lacks white tips on inner rectrices (all tail feathers more pointed than adult's), has white tips on some (mostly inner) greater coverts, white otherwise restricted to edges of tertials and bases of flight-feathers (usually less on juvenile female), only inner primaries narrowly tipped white; chin to bib and ventral line sooty brown. **VOICE.** Most frequent contact call a short series of thin whistles, usually introduced by slightly higher-pitched note, "ti, pee-pee-pee, ti-pee-pee-pee-pee" or "teep, whee-whee-whee-whee" or "wheh-wheh-wheh-wheh-wheh"; also a soft "tip-it!" and single mellow notes, including "pit" or "chit", and a sharper "tink" similar to that of Common Chaffinch (*Fringilla coelebs*). Song a thin, high-pitched "tiu-sut-sut-sut" and short ringing trill.

**Habitat.** Lowland dry acacia (*Acacia*) thorn-scrub (usually dominated by *Acacia catechu* and *Acacia nilotica*), generally in stony or hilly areas; also dry deciduous forest with scrub, and enters adjacent orchards and gardens. In SW of range, in Kerala, formerly occurred mostly in moist deciduous forests. At 375–920 m in S of range (Karnataka and Tamil Nadu).

**Food and Feeding.** Diet poorly known, but includes small invertebrates, principally spiders (Araneae) and larvae, and also some fruit, especially berries, and nectar. Usually in pairs or in small family parties of up to five individuals; occasionally in mixed-species foraging flocks. Fairly shy or wary. Forages at all levels in trees, but mainly in canopy; also in shrubs and sparse undergrowth.

**Breeding.** Poorly known. Season May–Aug. Nest a pad or platform of plant fibres and down, animal hair and wool, placed up to 2 m above ground in hole in tree, frequently in old hole of woodpecker (Picidae). No information on clutch size, but up to three fledglings recorded in one brood; nestlings fed by both parents. No further information.

**Movements.** Resident, but may disperse some distance from breeding area in non-breeding season.

**Status and Conservation.** VULNERABLE. Has declined considerably in both range and numbers over last century; distribution has probably always been patchy, but local declines and extinctions have exacerbated this tendency; overall numbers now reckoned to be very low. In NW part of range, sparse and sporadic in Kutch and N Gujarat, S & SC Rajasthan; perhaps always rare in S India, but even rarer now with no recent records from Andhra Pradesh and few from Karnataka and Tamil Nadu. In Rajasthan, 8 pairs found in Kumbhalgarh Wildlife Sanctuary and adjacent areas in 2004. Recorded in Anshi National Park (Karnataka) and on border of Mudumalai National Park (Tamil Nadu). Habitat now widely degraded and range fragmented; decline due mainly to depletion and destruction of habitat, largely through clearance for agriculture, fodder, human settlements and urban development, quarrying and gypsum-mining, and overgrazing; also cutting of trees for making charcoal; at one site in Kutch, *Acacia* bushes severely lopped (c. 100 bushes/day) to meet local demand for disposable toothbrushes. Main conservation target is strict protection of a network of patches of healthy habitat. Species largely replaced by *P. major* in areas of increasing urbanization.

**Bibliography.** Ali & Ripley (1983), Anon. (2006f), Butchart & Stattersfield (2004), Collar, Andreev *et al.* (2001), Collar, Crosby *et al.* (1994), Grimmett *et al.* (1998), Harrap & Quinn (1996), Hussain *et al.* (1992), Lott & Lott (1999), Rasmussen & Anderson (2005), Sharma (2004), Stattersfield & Capper (2000), Tehsin *et al.* (2005), Tiwari (1997, 2001), Tiwari & Rahmani (1997), Zacharias & Gaston (1993).

## 47. Black-lored Tit

### *Parus xanthogenys*

**French:** Mésange à joues jaunes **German:** Kronenmeise **Spanish:** Carbonero Carigualdo Indio  
**Other common names:** Black-lored Yellow Tit, Black-spotted Tit; Indian Yellow Tit (*aplonotus*)

**Taxonomy.** *Parus xanthogenys* Vigors, 1831, Simla-Almora district, Himalayas, India.

Forms a superspecies with *P. spilnotus*, and has in the past been considered conspecific. Races *aplonotus* and *travancorensis* have been treated as representing one or, alternatively, two separate species; they intergrade in Western Ghats (between Konkani and Hassan), in W of range, where intermediates described as additional race, *xanthonotus* (female with crown varying between black and greenish, or olive-greenish with darker spots, whitish-yellow face and sides of breast and belly contrasting with well-defined bib and ventral stripe). Three subspecies recognized.

**Subspecies and Distribution.**

*P. x. xanthogenys* Vigors, 1831 – NW & C Himalayas from N India E to E Nepal.

*P. x. aplonotus* Blyth, 1847 – C India.

*P. x. travancorensis* (Whistler & Kinnear, 1932) – Western Ghats, in W peninsular India.

**Descriptive notes.** 13–14 cm; 12.9–19.7 g. Medium-sized, crested, black and yellow tit. Male nominate race has forehead and lores to crown and pointed crest black, yellow nape extending upwards onto tips of longest crest feathers; yellowish supercilium (from just before eye) flaring behind eye and merging with yellow on nape, broad black eyestripe merging with black side of neck; upperparts yellowish-green, tinged olive, scapulars with blackish centres, uppertail-coverts greyish; tail blackish, fringed grey, all feathers tipped narrowly white, outer web of outermost rectrix white; upperwing-coverts blackish, median and

greater coverts broadly tipped pale yellowish, alula broadly tipped yellowish-white; flight-feathers blackish-grey, tertials fringed yellowish-white and broadly tipped white, secondaries and inner primaries finely fringed greyish and tipped white, outer primaries broadly white at base (forming small panel on closed wing); cheek, ear-coverts and marginally to upper neck side yellow; chin, throat and side of neck to centre of breast and centre of belly black, slightly glossed blue on throat and breast, sides of breast and belly lemon-yellow, flanks the same or washed olive, and undertail-coverts dark grey, tipped whitish; axillaries and underwing-coverts whitish; in worn plumage, upperparts duller, more grey-green, and dark centres of scapulars larger, cheeks and nuchal patch paler, fringes of flight-feathers reduced, and tips of rectrices abraded; iris dark brown; bill black; legs slaty blue-grey. Differs from *P. spilnotus* in black forehead and lores, longer black eyestripe, more uniformly green (less streaked) upperparts. Female is very like male, but has slightly duller crown and slightly shorter crest, and face and nuchal patch a shade paler yellow. Juvenile is as adult, but crown duller and crest shorter, upperparts duller, becoming greyer on rump and uppertail-coverts, tail with poorly defined whitish tips, wing coverts washed yellow; secondaries fringed grey, cheeks and ear-coverts pale yellow, small bib to centre of breast and ventral line dull brownish-black (paler on juvenile female), rest of underparts pale yellow, washed greyish on flanks, iris paler or greyer. Races fairly well defined: *aplonotus* is as nominate, but blackish on upper lores reaching eye, slightly duller olive-green upperparts, tips of wing-coverts and edges of flight-feathers white, and yellow on face, neck side and underparts somewhat duller or paler, female has paler yellow face and underparts and greyish-olive throat, bib and narrower ventral stripe; *travancorensis* is duller than nominate, dull olive-grey above, rectrices with fine white tips, cheeks pale whitish-yellow, underparts paler yellow and heavily tinged olive, female variable (possibly polymorphic), either as male, or with crown, crest and upperparts olive-grey, face paler or duller than male and eyestripe slightly darker than crown, and throat, bib and ventral stripe olive-grey (on some greenish-olive and little different from rest of underparts, and yellow may be restricted to faint line at side of breast). **VOICE.** Calls include "si-si", "tsi-tsi-pit-tui", "tzee-tzee-wheep-wheep-wheep", also a rattling "ch-chi-chi-chi-chi" like that of a nuthatch (Sitta), and a sharp "tst-reet" alarm note; calls very similar to those of *P. spilnotus*. Song, Jan–Sept in Nepal but mostly Mar and Apr, a series of short disyllabic or trisyllabic musical whistles on different pitches, repeated in quick succession, occasionally louder as e.g. "der-twink, der-twink, der-twink", also as "pui-pui-tee, pui-pui-tee", "tsi-teuw, tsi-teuw" or more strident "tsi-wheeah-wheeah"; in C India, race *aplonotus* song similar to that of nominate, but usually with short and higher-pitched introductory note or series of short, high notes, including "tititit-krak-rak-brzt" and "ti-ti-kit-fzew", also a hard "ti-whit".

**Habitat.** Open submontane and montane subtropical forests, mostly of oak (*Quercus*) or pine (*Pinus*), or evergreen forest; also in mixed bamboo jungle and secondary forest, scrub and scattered trees, ban oak (*Quercus incana*) jungle and wooded edges of cultivation, especially coffee plantations, cardamom sholas, and occasionally gardens. In Himalayas breeds at 850–2400 m, possibly to 2950 m in Nepal, and in peninsular India at 600–1830 m; in non-breeding season, also down to c. 915 m (exceptionally as low as 75 m).

**Food and Feeding.** Food includes small invertebrates and larvae, mainly spiders (Araneae), ants (Formicidae) and cockroaches (Blattodea); also fruit, including mulberries (*Morus*) and raspberries (*Rubus*), also flower buds and nectar. Usually in pairs or in small, probably family, groups; in non-breeding season joins mixed-species foraging flocks with small babblers (Timaliidae), flycatchers (Muscicapidae), minivets (*Pericrocotus*), white-eyes (*Zosterops*), leaf-warblers (*Phylloscopus*) and nuthatches (Sittidae). Actively and acrobatically forages in trees, usually at middle to upper canopy level; rarely descends to undergrowth. Clings upside-down on leaves and slender twigs; occasionally pursues insects, especially flying ants, in flight.

**Breeding.** Season Mar–Jun in Himalayas, in peninsular India Apr–Aug in N, Jul–Oct in S and Jun–Nov in Western Ghats; possibly two broods. Nest built by both sexes, mostly of moss, lichens, plant fibres, wool and animal hair or fur, up to 7 m from ground in natural hole or cavity in tree, occasionally in disused hole of woodpecker (Picidae) or barbet (Capitonidae), or in hole excavated by birds themselves in rotting stump or branch; hole in building or in earth bank also recorded as used. Clutch 4–5 eggs; both parents feed and care for nestlings; no information on incubation and fledging periods.

**Movements.** Resident, with some short-distance altitudinal movements to lower levels in non-breeding season; has occurred in Salt Range, in N Pakistan.

**Status and Conservation.** Not globally threatened. Common or locally common, but absent from large areas of apparently suitable habitat; in Nepal, rare E of Arun Valley. Before 1930s breeding range extended W to Murree Hills, in N Pakistan, but now only a rare winter visitor there.

**Bibliography.** Ali & Ripley (1983), Fleming *et al.* (1979), Gill *et al.* (2005), Grimmett *et al.* (1998), Hailman (1994), Harrap & Quinn (1996), Inskipp & Inskipp (1991), King *et al.* (1975), Martens & Eck (1995), Rasmussen & Anderton (2005), Roberts (1992), Stuart Baker (1932), Vaurie (1950).

## 48. Yellow-cheeked Tit

### *Parus spilonotus*

**French:** Mésange à dos tacheté **German:** Königsmeise **Spanish:** Carbonero Carigualdo Chino  
**Other common names:** Black-spotted Yellow Tit; Chinese Yellow Tit (*rex*)

**Taxonomy.** *Parus spilonotus* Bonaparte 1850, Darjeeling, India.

Forms = superspecies with *P. xanthogenys*, and has in the past been considered conspecific. Races intergrade widely. Four subspecies recognized.

**Subspecies and Distribution.**

*P. s. spilonotus* Bonaparte, 1850 – E Himalayas from E Nepal E to NE India (including N Assam), N & W Myanmar and SW China (S Xizang).

*P. s. subviridis* Blyth, 1855 – NE India (S Assam S to Manipur), Myanmar (except N, W & C), N Thailand and S China (W Yunnan).

*P. s. rex* David, 1874 – S & SE China (S Sichuan and S & E Yunnan E to Fujian and S Zhejiang), N Laos and NW Vietnam.

*P. s. basileus* (Delacour, 1932) – S Laos and SC Vietnam.

**Descriptive notes.** 14–15.5 cm; 18–23 g. Medium-sized to large size tit with erect black crest and eyestripe and yellow cheeks. Male nominate race has forehead and lores to supercilium and nuchal spot yellow, crown and crest to side of nape black, yellow nape extending upwards onto tips of longest crest feathers; broad black eyestripe from eye to rear ear-coverts; upperparts olive-green (greener in NE Myanmar), tinged yellow, with blackish centres of mantle, back and scapular feathers, rump slightly greyish; tail black, fringed bluish-grey, all feathers narrowly tipped white, outer web of outermost feather white; upperwing-coverts

black, median and greater coverts broadly tipped white, alula finely tipped white; flight-feathers blackish-grey, tertials narrowly fringed pale grey and broadly tipped white, secondaries and primaries fringed bluish-grey, outer primaries broadly white at base (forming short panel on closed wing); cheeks, ear-coverts and side of neck yellow; chin, throat (including side of throat) to centre of breast and continuing in irregular line to centre of belly black, slightly glossed blue on throat and breast; sides of breast and belly pale olive, tinged yellowish, flanks the same or greyish-olive, undertail-coverts dark grey, tipped whitish; underwing-coverts blackish, broadly tipped white; in worn plumage, upperparts duller or greyer and dark centres of mantle and scapulars larger, fringes of flight-feathers reduced, white tips of tail abraded, ventral line slightly broader, rest of underparts paler; iris brown; bill dark greyish-horn or black; legs slate-blue to grey. Differs from *P. xanthogenys* mainly in yellow forehead and lores, green mantle streaked blackish, and whitish wingbars. Female differs from male in having wingbars yellowish-white, fringes of flight-feathers olive and bib slightly duller. Juvenile is as adult, but crown duller, crest shorter, face and nuchal patch paler, upperparts duller, becoming greyer on rump and uppertail-coverts, whitish tail tips poorly defined (or absent), upperwing-coverts as adult but duller and tipped yellowish, secondaries fringed grey and tertials fringed olive-grey, cheeks and ear-coverts pale yellow, small dull brownish-black (paler on juvenile female) bib to centre of breast and ventral line to centre of belly, rest of underparts pale yellow, greyish wash on flanks. Racial variation fairly well defined: *subviridis* is as nominate, but slightly darker olive upperparts, dark centres showing as scales, tips of upperwing-coverts white or washed yellowish, neck side and underparts slightly duller or paler, flanks washed greyish-olive, female has more uniform and less scaled mantle, flight-feather edges light olive, bib and ventral stripe olive-yellow or absent; *rex* is as nominate, but male has yellow on head richer, eyestripe broader and blacker, upperparts bluish-grey and broadly streaked blackish, more extensive black below (reaching to side of neck, entire breast and broadly to centre of upper belly), flanks greyish, undertail-coverts whiter, female similar to male but crown duller, upperparts olive-grey and diffusely streaked darker, bib and ventral stripe olive-grey and often little different from rest of underparts; *basileus* is intermediate between previous two, but mantle with variable olive tinge, lacks black on neck side, yellow of face merges with paler or duller yellow on sides of breast, belly whitish, flanks greyish-olive, female similar to that of *rex* but yellower, less grey. VOICE. Calls include “si-si-si” or more drawn-out “si-si-pudi-pudi”, or “tsee-tsee-tsee, si-si” or “ki-ki beer, ki-ki beer, ki-ki beer, ki-ki beer”, and a “witch-a witch-a witch-a”, often in combination with prolonged “churr-r-r-r-r-r” (like similar note of *Cyanistes caeruleus*), also a harsh “krrank-it, krrank-it, krrank-it”; calls generally similar in tone and quality to those of *P. major*. Song a rapid repetition of 3-note, ringing phrase, “chiu-chiu-piu, cha, chiu-chiu-piu, cha, chiu-chiu-piu, cha” or “dzi-dzi-pu, dzi-dzi-pu”.

**Habitat.** Open temperate and subtropical deciduous or mixed forests with oak (*Quercus*), pine (*Pinus*) and rhododendron (*Rhododendron*), also secondary forest, bamboo, edges of (usually well-wooded) cultivation, including plantations and areas with scattered trees; in SE Asia also favours evergreen hill forests and large gardens. In Nepal breeds at 1980–2440 m, in NE India at 1200–2450 m, and in N & E Myanmar at 800–2750 m; in China, above 1000 m in NW Fujian, 1200 m in Sichuan and at 1140–3050 m in Yunnan; breeds at 900–1675 m in Thailand, above 800 m in S Laos and, in Vietnam, at 600–1700 m in NW and 800–2285 m in S. In non-breeding season also at lower levels, down to 450 m in E Nepal, 500 m in Arunachal Pradesh (also up to 3100 m in Oct), and in China down to c. 350 m in Guizhou and N Guangdong, 500 m in N Guangxi, and at 600–700 m in Zhejiang.

**Food and Feeding.** Diet not well known, but includes small invertebrates and larvae, including spiders (Araneae), also buds and some fruit, e.g. berries. Usually in pairs or small family parties; in non-breeding season in mixed-species foraging flocks with other tits and small babblers (Timaliidae). Fairly tame and often confiding, and noisy. Actively forages in middle and lower levels of forest trees, also in shrubs and undergrowth.

**Breeding.** Season late Feb to mid-Aug. Nest a small platform or pad of moss, grass, bracken (*Pteridium*) strips, leaves, animal fur, wool and feathers, sometimes supplemented with other locally available items e.g. flower petals and snakeskin, placed up to 15 m above ground in hole in tree, less frequently in hole in wall or rocky bank. Clutch 4–6 eggs. No further information.

**Movements.** Resident; also short-distance altitudinal migrant, descending to lower levels in non-breeding season.

**Status and Conservation.** Not globally threatened. Common or locally common to rare. Scarce or rare in Himalayas, but locally common in NE Indian hill states and Myanmar. Common in N Thailand; fairly common in N Vietnam, and recently recorded as breeding in E Tonkin (Ha Giang province). In China generally uncommon, but locally common in NW Fujian, N Guangdong and SE Yunnan. Since 1988 range in China has expanded S into Hong Kong, where small population now resident; was previously an irregular non-breeding visitor in Hong Kong.

**Bibliography.** Ali & Ripley (1983), Cheng Tsohsin (1987), Etchécopar & Hüe (1983), Fleming *et al.* (1979), Gill *et al.* (2005), Grimmett *et al.* (1998), Harrap & Quinn (1996), Inskipp & Inskipp (1991), King *et al.* (1975), Lekagul & Round (1991), MacKinnon & Philipps (2000), Meyer de Schauensee (1984), Pui Lok *et al.* (2005), Rasmussen & Anderton (2005), Robson (2000, 2005a), Smythies (1986), Spierenburg (2005), Stuart Baker (1932), Vogel *et al.* (2003).

## 49. Yellow Tit

### *Parus holsti*

**French:** Mésange de Taiwan **German:** Taiwanmeise **Spanish:** Carbonero de Formosa  
**Other common names:** Formosan Yellow Tit

**Taxonomy.** *Parus holsti* Seebohm, 1894, Taiwan.

Molecular studies indicate closest relatives are *P. xanthogenys* and *P. spilonotus*. Monotypic.

**Distribution.** Taiwan.

**Descriptive notes.** 12.5–13 cm. Small tit with long erect crest. Male has forehead, crown and crest to side of nape black, glossed bluish, white nuchal patch extending upwards onto tips of longest crest feathers; upperparts black glossed bluish-green; tail black, broadly fringed blue (variably iridescent to bright pale blue), all feathers narrowly tipped white, outer web of outermost feather white; upperwing black, greater coverts grey or greyish-blue, narrowly tipped white, tertials broadly fringed iridescent blue and broadly tipped white, secondaries and primaries edged iridescent blue, narrow white tips on secondaries; lores

to eye and cheek, ear-coverts and neck side to breast and belly deep yellow, small blackish spot in front of eye, side of lower breast and flanks paler or washed greyish, vent dull black, undertail-coverts yellowish-white; axillaries and underwing-coverts whitish; iris brown or deep reddish-brown; bill black; legs slate-grey to blue-grey. Female is similar to male, but forehead to crest sooty black, glossed bluish, crown side and upperparts to rump dull olive-green, blue fringes on tail duller or greyer, median and greater upperwing-coverts bluish-grey, tipped bright pale grey, edges of flight-feathers slightly duller or greyer, lacks black on vent. Juvenile has forehead to crown and crest bluish-grey, tips of crest whitish, upperparts duller blue and washed olive-green, wing and tail as adult, face pale creamy yellow, underparts white or sometimes washed yellowish. VOICE. Calls include “si-si-si” or more drawn-out and insect-like “tzee-tzee-tzee”, often in combination with other notes e.g. “si-si-si dza-dza-dza” or “tsi-tsu-tsi, tsu-dza-dza-dza” and variations, including “tsut, tsut” and thin buzzing “dzi-dzi-dzi”; alarm a prolonged, scolding “dz-za-za-za”; all calls very similar to those of *P. major*. Song, apparently restricted to breeding season, a series of 3 or 4 ringing notes, mainly variations of “tea-cher” theme, e.g. frequently repeated “tu-wich-chi, tu-wich-chi, tu-wich-chi...” or “pipi-chu, pipi-chu, pipi-chu” or slightly harsher and buzzing “chich-chich-zu, chich-chich-zu, chich-chich-zu”. Female also sings, but song generally less musical than that of male.

**Habitat.** Breeds in temperate primary broadleaf forests, occasionally in mixed and secondary woodlands, usually at 1000–2500 m. In non-breeding season more often along forest edges and occasionally edges of human settlements; recorded down to 700 m.

**Food and Feeding.** Diet poorly known, but includes small invertebrates and larvae; nestlings apparently fed largely with caterpillars. Occurs singly and in pairs; occasionally, joins mixed-species foraging flocks. Forages in upper and canopy levels of forest trees and in tops of shrubs in lower undergrowth.

**Breeding.** Poorly known. Breeds in Apr. at least. Nest mostly of dried leaves, bamboo, lichens, moss and feathers, placed up to 7 m above ground in hole or cavity in tree trunk; nest apparently reused in subsequent years, with new material added. Clutch 3–4 eggs. No further information.

**Movements.** Resident, with some short-distance movements undertaken. Recorded at lower elevations in non-breeding season, but also up to 2500 m at same time of year.

**Status and Conservation.** Not globally threatened. Currently considered Near-threatened. Restricted-range species; present in Taiwan EBA. Uncommon or rare; possibly more numerous in S & W mountains. Has declined as a result of large-scale destruction of broadleaf forest; does not adapt well to more marginal habitats, where meets competition from *P. monticolus*. Is also illegally sought after by bird-trappers for cagebird trade.

**Bibliography.** Anon. (2006), Butchart & Stattersfield (2004), Chung Wuan Fu & Severinghaus (1979), Cheng Tsohsin (1987), Etchécopar & Hüe (1983), Gill *et al.* (2005), Harrap & Quinn (1996), MacKinnon & Philipps (2000), Meyer de Schauensee (1984), Stattersfield & Capper (2000).

## 50. White-fronted Tit

### *Parus semilarvatus*

**French:** Mésange à front blanc **German:** Weißstirnmieise **Spanish:** Carbonero Frentiblanco

**Taxonomy.** *Melaniparus semilarvatus* Salvadori, 1865, Himalayas.; error = Luzon, Philippines. Sometimes placed in a separate genus, *Sittiparus*. Three subspecies recognized.

**Subspecies and Distribution.**

*P. s. snowi* Parkes, 1971 – NE Luzon (N Sierra Madre Mts), in N Philippines.

*P. s. semilarvatus* (Salvadori, 1865) – C & S Luzon (C & S Sierra Madre Mts).

*P. s. nehrkorni* (A. W. H. Blasius, 1890) – Mindanao, in S Philippines.

**Descriptive notes.** 13 cm. Medium-size, large-billed and long-tailed tit with mostly black plumage. Male nominate race has forehead and upper lores white or pale buffish, rest of head, upperparts and underparts blackish-brown, glossed deep indigo-blue above, glossed bluish only on breast below, concealed whitish nuchal patch at base of nape feathers; tail brownish-black, fringed deep blue-black, upperwing brownish-black, median and greater wing-coverts fringed indigo-bluish;

axillaries and underwing-coverts whitish; iris brown to pale brown; bill and legs black. Female is similar to male, but buffish-white on forehead extends diffusely to cheeks, upperparts slightly duller, underparts (lacking gloss except faintly on breast) paler or more ochre-brown, longest undertail-coverts tipped white. Juvenile is as female, young male usually darker or blacker below, and with slightly paler tips of greater coverts. Racial variation slight to moderate: *snowi* male is on average slightly duller, less glossy, above and below, has larger nuchal patch (still concealed, except in juvenile plumage, when appears as narrow

white half-collar), and whiter bases on inner webs of flight-feathers and on undertail-coverts, female slightly duller than nominate, browner on underparts, may show white spots on nape (nuchal patch not always concealed), and usually more white on tips of primary coverts on underwing; *nehrkorni* differs from previous in more extensive white bases on primaries and outer secondaries, axillaries more extensively white, also cheeks and ear-coverts may be whitish, juvenile similar to juvenile of previous, with dull white nuchal patch and more white on undertail-coverts. **VOICE.** Calls include short sharp "psit" and higher-pitched rolling "tsuit" or metallic "zeeeeet", repeated several times or combined into longer "sit-tsuit-suit-suit"; also high-pitched "tsi-tsi-tsi-tsi" or

"zit-zit-zit-zit", sometimes introduced or followed by "tsre" or "tsree", and a longer "tsee-tsi-tsi". Song is apparently a much longer version of call notes accelerating towards end, "tsi-tsi-tsi-tsi-tsi-tsi-tsi-tsi-tsi-tsi"; also gives metallic and rising trill, "i-i-i-i-i, tji", followed by lower "djididididiw".

**Habitat.** Lowland and hill forest, including forest edges, secondary forest and woodlands, degraded and logged forest, also occasionally in scrubby areas; to 1150 m.

**Food and Foraging.** Diet not well known, but presumed to include small invertebrates and larvae. Usually alone, in pairs or in groups of up to ten individuals, also in mixed-species foraging flocks. Shy and elusive. Forages in middle and upper levels of trees, moving from one canopy to the next; also occasionally in undergrowth. Uses fairly rapid gleaning action.

**Breeding.** Very poorly known. Pair prospecting nest-hole in tree stump in early Feb, adult feeding fledged juvenile mid-Mar, and adult in breeding condition in May. No other information.

**Movements.** Resident.

**Status and Conservation.** Not globally threatened. Currently considered Near-threatened. Restricted-range species: present in Luzon EBA and Mindanao and the Eastern Visayas EBA. Generally rare or uncommon; locally common in Sierra Madre, in N Luzon. Very few recent observations from Mindanao (race *nehrkorni*), where known from eight localities. Rapid and large-scale destruction of forests in recent years in Philippines has seriously reduced the amount of suitable habitat available to this little-known and generally shy and retiring species.

**Bibliography.** Anon. (2006f), Butchart & Stattersfield (2004), Collar *et al.* (1999), Dickinson *et al.* (1991), Gilliard (1950), Hachisuka (1930), Harrap & Quinn (1996), Kennedy *et al.* (2000), Parkes (1971), duPont (1971), Stattersfield & Capper (2000), Worcester & Bourns (1898).

## Family PARIDAE (TITS AND CHICKADEES) SPECIES ACCOUNTS

### Genus *PSEUDOPODOCES*

Zarudny & Loudon, 1902

#### 51. Ground Tit

##### *Pseudopodoces humilis*

**French:** Mésange de Hume **German:** Tibetmeise **Spanish:** Carbonero Terrestre  
**Other common names:** Groundpecker, Hume's Groundpecker/Ground Chough/Ground Jay, Brown Ground Chough, Tibetan Ground Jay

**Taxonomy.** *Podoces humilis* Hume, 1871, Sanju Pass, Xinjiang, north-west China. Until recently placed with the crows in family Corvidae, often in the ground-jay genus *Podoces*; osteological, morphological and vocal characters, however, indicate that it belongs in present family, a treatment supported by mitochondrial DNA evidence. E birds sometimes separated as race *saxicola*. Monotypic.

**Distribution.** SW & C China (SW Xinjiang and S & E Qinghai-Xizang Plateau E to Ningxia and Gansu, S to S & SE Xizang, NE Yunnan and W Sichuan), also SE Ladakh, N Nepal and Sikkim.

**Descriptive notes.** 19–20 cm; 42.5–48.5 g. Large, upright, long-feathered or fluffy-looking terrestrial tit with long, curved bill. Forehead pale buff, crown and upperparts grey-brown, tinged sandy, slightly paler on side of crown and rump; broad whitish-buff half-collar on lower nape; central tail feathers dark brown, outermost two pairs buffish-white; upperwing slightly browner than upperparts, alula black, broadly tipped white; primary coverts and flight-feathers dark brown, broadly fringed pale buffish-brown; lores black, cheek and ear-coverts sandy buff; throat and underparts off-white, warm buff tinge on throat to breast side; iris dark brown; bill and legs black. Sexes alike. Juvenile is similar to adult, but upperparts more buffish, paler collar on nape, lacks black on lores and is faintly mottled on face, barred on throat, bill straight and shorter, legs paler. Voice. Usually silent. Call a weak or soft, drawn-out "cheep" and shorter "chip"; clear, downslurred "cheer" or "sque" frequently repeated, also a ringing "veet"

and a strident "scree-sich-ich". Song appears to be a longer version of call, usually introduced with "chip" note before running into rapidly whistled but fairly hoarse scolding "cheep-cheep-cheep-cheep", rising and then falling in pitch.

**Habitat.** Treeless steppes, including grassy plains and rocky hills with scattered stunted bushes above tree-line, often in yak pastures and close to human settlements, including monasteries. At 3100–5500 m in SW China, 4200–5500 m in Ladakh and 3965–5335 m in Nepal Himalayas.

**Food and Feeding.** Diet largely unknown; presumably includes small invertebrates and larvae. Usually solitary or in pairs; occasionally in small groups, possibly family parties. Spends most time on ground, occasionally perches on rocks or walls; usual gait is long bounding hops. Probes in soft earth, turf, yak dung and decaying animal corpses. Flight weak or fluttering and low over ground (but may fly for some distance); evades predators by hopping. Frequently associates with pikas (*Ochotona*).

**Breeding.** Poorly known. Season Apr–Jul. Co-operative breeder. Nest mostly of moss, dry plant fibres and animal hair, placed in deep hole or tunnel (up to 2 m long) in soft ground, bank or stone wall, either excavates own hole or utilizes that of a pika. Clutch 4–6 eggs; nestling period thought to be up to 25 days; well-developed young beg food from adults for some time after fledging. No other information.

**Movements.** Resident, but birds in Ladakh may be scarce residents or occasional summer breeding visitors, Mar–Oct.

**Status and Conservation.** Not globally threatened. Locally common in China; frequent in Nepal and rare in Ladakh.

**Bibliography.** Borecky (1978), Cheng Tsohsin (1987), Étiéhenkopar & Hile (1983), Gebauer *et al.* (2004), Gill *et al.* (2005), Grimmett *et al.* (1998), Harrap & Quinn (1996), Hartert (1903c), James *et al.* (2003), Johannessen *et al.* (2006), Lei Fumin *et al.* (2003), Londei (1998, 2002), MacKinnon & Phillips (2000), Madge & Burn (1993), Meyer de Schauensee (1984), Rasmussen & Anderton (2005), Robson (1994), Vaurie (1954a), Wang Gang *et al.* (2003).

## Genus *CYANISTES* Kaup, 1829

### 52. Common Blue Tit

#### *Cyanistes caeruleus*

**French:** Mésange bleue **German:** Blaumeise **Spanish:** Herrillo Común  
**Other common names:** Blue Tit; African Blue Tit (*ultramarinus* and *cyrenaicae*, often with *C. teneriffae*); Pleske's Tit (hybrid form "*pleskii*")

**Taxonomy.** *Parus caeruleus* Linnaeus, 1758, Sweden.

Until recently present genus normally subsumed into a broad *Parus*, and many authors still prefer that treatment. Forms a superspecies with *C. teneriffae* and *C. cyanus*. Previously considered conspecific with former, but differs in mitochondrial DNA; alternatively, races *ultramarinus* and *cyrenaicae* alone frequently treated within *C. teneriffae*; further study required. Hybridizes with *C. cyanus*, especially following years when latter expands W in irruptive manner (hybrids described as a separate taxon, "*pleskii*"); hybridizes rarely also with *Parus major*. Nominote race intergrades with *obscurus*, *ogliastrae* and *satunini*; also, *satunini* intergrades with *persicus*, and it is uncertain which of these races breeds in NW Syria. Eleven subspecies recognized.

**Subspecies and Distribution.**

- C. c. obscurus* (Prazák, 1894) – British Is.
- C. c. caeruleus* (Linnaeus, 1758) – N, C & E Europe (S to N Spain, Italy, N & C Greece), W & N Asia Minor.
- C. c. ogliastrae* (E. J. O. Hartert, 1905) – S Iberia, Corsica and Sardinia.
- C. c. balearicus* (Jordans, 1913) – Mallorca.
- C. c. calamensis* (Parrot, 1908) – S Greece, Cyclades, Crete and Rhodes.
- C. c. orientalis* Zarudny & Loudon, 1905 – SE European Russia.
- C. c. satunini* Zarudny, 1908 – Crimea, Caucasus, E Turkey, N Jordan, NW Iran, possibly also SE Turkey, NW Syria and N Iraq.
- C. c. raddei* (Zarudny, 1908) – N Iran.
- C. c. persicus* (Blanford, 1873) – SW Iran.
- C. c. ultramarinus* (Bonaparte, 1841) – NW Africa from Morocco E to N Tunisia.
- C. c. cyrenaicae* (E. J. O. Hartert, 1922) – NE Libya.

**Descriptive notes.** 11–12 cm; 7.5–14.7 g. Small, small-billed, compact tit with rounded head shape. Male nominate race has forehead and upper lores white and merging with white supercilia, which join on centre of nape; forecrown blue, becoming deeper blue on hindcrown; lores and eyestripe narrowly blackish, merging with deep blue on lower nape and side of neck; centre of lower nape and upper mantle pale greyish-blue, rest of mantle, back and scapulars bluish-green, rump lighter, more yellowish-green, uppertail-coverts bright blue; tail blackish-blue, broadly fringed bright blue, outermost rectrix narrowly fringed whitish;

upperwing-coverts and alula greyish, broadly fringed deep blue, greater coverts tipped white (forming narrow wingbar), flight-feathers dark grey, broadly fringed bright blue, tertials broadly tipped whitish; cheek and ear-coverts white; chin and upper throat black, merging narrowly across throat side with deep blue on lower side of neck; underparts yellow, tinged greenish-olive on breast, brighter yellow on flanks, centre of breast may show narrow blackish line (often concealed), and centre of belly may be whitish; undertail-coverts creamy; axillaries and underwing-coverts yellow; in worn plumage, slightly bluer on crown, flight-feathers and tail, upperparts greyer or less green, white tips of greater coverts and flight-feathers abraded or absent, bib slightly darker black, and blackish line on centre of breast often more prominent; iris dark brown to blackish-brown; bill dark slate to black, paler cutting edges; legs slaty to blue or slate-grey. Female is on average slightly

duller than male, but otherwise very similar. Juvenile has forehead, supercilium and centre of nape dull yellow, crown and neck side darker, upperparts greyer, tail duller blue, upperwing-coverts fringed with greenish-blue, tips of greater coverts and tertials yellowish-white, flight-feathers edged greyish-blue, face and underparts dull yellow (becoming whiter with age), grey on chin and upper throat, and no dark central line on breast. Races differ mainly in colour tones, both above and below; *obscurus* is as nominate, but crown slightly darker blue, mantle slightly darker or greener (less bluish-grey), white tips on greater coverts and tertials slightly narrower, underparts deeper yellow with usually obvious narrow line on central breast; *ogliastrae* is similar to previous, but mantle slightly bluer, wing-coverts deeper blue, underparts bright yellow, female often as brightly coloured as male; *balearicus* is as nominate, but mantle paler or greyer, underparts slightly paler, whiter on breast and belly, line on centre of breast narrower; *calamensis* is very like nominate but slightly smaller; *orientalis* is as nominate, but upperparts olive-grey, tinged yellowish, and underparts brighter or paler yellow; *satunini* is also as nominate, but upperparts slightly darker, olive-grey, underparts pale yellow, flanks greyish; *raddei* is as last, but upperparts slightly darker olive (and less grey), underparts deep yellow; *persicus* has shorter and thinner bill, upperparts pale bluish-green, tinged greyish, underparts variable, from rich yellow on breast and whiter on belly and undertail-coverts to uniform whitish-yellow; *ultramarinus* resembles nominate, but crown black with glossy dark bluish tips, broad black eyestripe (narrow across lores) merging broadly on side of nape with black of hindneck, upperparts mostly dark bluish-grey (rump may be tinged greenish), tertials and secondaries broadly tipped white, lower neck side, chin and upper throat broadly black, underparts deep yellow with pronounced blackish ventral line; *cyrenaicae* is as last but slightly smaller, and has narrower white band on forehead, darker or duller blue mantle, slightly duller yellow underparts. **VOICE.** Very vocal. Contact note between partners or members of flock (frequently used throughout year) a short and thin "tsee", singly or in series; scolding or churring "churrurr", rising towards end, with varying emphasis, given especially in alarm or at approach of predator, may be preceded or followed by single or multiple sharp "tsee" or thin, high-pitched "seeee" or "pit" notes, e.g. "pit pit churr" or "drrrrrrr tit tit tit", and frequently repeated when agitated; in N Africa also sharp calls similar to song of European birds, "tsee-tsi-brree tsee-tsi-brree" or "chi-chichiwee" and a more metallic "pichoo". Also high-pitched "zeedle" by both sexes during courtship and copulation; female on nest also gives short, explosive hissing note in aggressive defence display to intruder or predator; nestlings and recently fledged birds high-pitched and almost incessant "tsee-tsee-tsee-tsee-tsee-tsee". Song a clear, high-pitched and lilting "tsit-sit-sissiwit" or "tsee-tsee-tsee-tsu-tsuühühühühühü" or "psi-psi-tsatsata, psi-psi-tsatsata", frequently repeated after short pauses, also shorter variations, including "tsee-tsee see-see", "siss-seedo" or "psi-dada, psi-dada, psi-dada"; individual males have repertoire of 3–8 songs, and song of female similar to male's. Geographical variation not marked within Europe, but songs in Europe differ from those in NW Africa; race *ultramarinus* has song closer to that of *Parus major*, with series of disyllabic metallic "tizi" notes (songs on Corsica and Mallorca somewhat similar).

**Habitat.** In Europe, mostly lowland and submontane deciduous woodlands, principally containing oak (*Quercus*) and birch (*Betula*), and broadleaf evergreen woods, also thickets, copses, hedgerows, areas of scrub with scattered trees, edges of cultivation, orchards, parks and gardens, including suburban areas and city centres; generally avoids large stands of conifers, although occurs in mature conifers in non-breeding season when in mixed flock. In E Mediterranean, occurs in high-altitude pine (*Pinus*) and oak in Jordan, cedar (*Cedrus*) forest in NW Syria and montane oak woodlands in Iran; in more arid areas in SE parts of range occurs mainly in riverine woodland, parks and gardens. In N Africa in cork oak (*Quercus suber*) forest and in Atlas oak (*Quercus faginea*) and evergreen oak (*Quercus ilex*), also cedar and montane juniper (*Juniperus*) forests in Morocco and N Libya; farther S, resident in palm groves of Saharan oases. In non-breeding season generally found in wider range of habitats containing trees and shrubs, but also in reedbeds. Sea-level to mountains: in breeding season to 1540 m in Austrian Alps, to 1700 m in Switzerland (most breeding below 1250 m), to 1800 m in Pyrenees, to 1525 m in Greece, Turkey and NW Iran (exceptionally up to 2000 m in Greece), and to at least 2040 m in SW Iran; in Caucasus breeds up to tree-line at c. 3500 m; to 1800 m or higher in Morocco.

**Food and Feeding.** Food includes small (usually c. 1 cm) invertebrates and larvae, also some fruit and seeds. Animal items principally springtails (Collembola), grasshoppers (Orthoptera), damselflies (Odonata), earwigs (Dermaptera), bugs (Hemiptera), moths (Lepidoptera, especially of family Tortricidae), lacewings (Neuroptera), spiders (Araneae), flies (Diptera), woodlice (Isopoda), ants (Formicidae), beetles (Coleoptera), harvestmen (Opiliones), millipedes (Diplopoda), slugs and snails (Gastropoda), ticks (Acari). Fruit and seeds, taken mainly in non-breeding season, include those of pine, cypress (*Chamaecyparis*), spruce (*Picea*), yew (*Taxus*), ash (*Fraxinus*), birch, beech (*Fagus*), box (*Buxus*), sycamore and maple (*Acer*), chestnut (*Castanea*), oak, olive (*Olea*), mulberry (*Morus*), fig (*Ficus*), mistletoe (*Viscum*), blackberry (*Rubus*), currant (*Ribes*), plums and cherries (*Prunus*), apple (*Malus*), pear (*Pyrus*), elder (*Sambucus*), rose (*Rosa*), hawthorn (*Crataegus*), dogwood (*Cornus*), snowberry (*Symphoricarpos*), walnut (*Juglans*), honeysuckle (*Lonicera*), sea-buckthorn (*Hippophae*), privet (*Ligustrum*), nightshade (*Solanum*), knapweed (*Centaurea*); also takes sap of birch, sycamore, maple, poplar (*Populus*), walnut and vine, and nectar from flowers of willow (*Salix*), plum, cherry, currant, aloe (*Aloe*), *Hibiscus* and *Tecomaria* in spring. Details of diet determined largely by seasonal abundance of various items. Solitary, in pairs or, in autumn, in small family groups; in autumn and winter sometimes in larger flocks, e.g. in SE of range flocks containing several hundred individuals recorded; also in mixed-species flocks in non-breeding season. Partners usually remain close to breeding territory during non-breeding season and forage with other insectivorous species, including Long-tailed Tit (*Aegithalos caudatus*), Goldcrest (*Regulus regulus*) and Eurasian Treecreeper (*Certhia familiaris*), in roving flock, range of which (up to 10 ha) includes several breeding territories. Winter flocks gradually reduced in size towards end of winter as pairs re-establish breeding territories. Active, agile and restless. Forages at all levels in trees, bushes and shrubs, occasionally on ground but usually only very briefly. Examines leaves, buds and slim branches with great thoroughness (may spend up to 30 minutes in single tree), but in winter often moves rapidly through foliage when foraging. Frequently hangs by one leg from slender twigs or leaves; easily locates insects under loose bark (which it strips) or in leafmines or galls; gleans foliage, feeds on aphids (Aphidoidea) gathered on bushes; taps reeds to locate concealed larvae. Hovers briefly while inspecting foliage, and occasionally pursues insects in flight. Visits birdtables and feeders, where it takes household scraps, including bread, cheese, fat, peanuts and variety of seeds, especially of sunflowers (*Helianthus*); large seeds taken to nearby branch, where opened while held in foot or wedged in bark and hammered with rapid strikes of the bill. Well known in parts of range (e.g. Britain) for its habit of piercing milk-bottle tops on doorsteps in order to sip cream; in more extreme cases, has been known to peck at and remove fresh putty from windows.

**Breeding.** Season Apr to late Jun, with egg-laying, clutch size and breeding success closely linked to timing of emergence and abundance of caterpillars (principally of *Tortrix* moths); two broods frequent in parts of Europe, but rare Britain, Germany, Corsica and Morocco. Monogamous, but polygamous males not infrequent where breeding density high; pair-bond usually lifelong. Territorial and solitary breeder; territory usually well defined by early Feb, and defended against interlopers, but pairs sometimes nest in close proximity, including case of two pairs in same nestbox; all females mated to polygamous male nest within single territory, and male feeds young in all nests. Male display includes slow moth-like flights and glides towards perched female, interspersed with intervals when crest partly raised and tail spread; male may also make vertical flight up to at least 6 m, then dive vertically to low branch; he also dances with body horizontal, tail fanned and slightly raised, nape feathers raised (showing dark blue collar), wings spread but tips drooped, and hops towards nest-site by pivoting along branch for up to 5 m before flying back and repeating the display; courtship of female involves provision by male of high-protein food items through egg-laying and incubation periods. Nest, built by female, mostly a cup of moss, dried grass, fine bark strips, plant fibres, leaves, animal hair and feathers, placed in hole or cleft in tree, or hole in post (including metal signpost) or other artificial site, e.g. wall, occasionally in old nest of other bird (or in foundations of large disused nest), rarely in hole in ground; nestboxes widely used; territory size usually within 1 ha, often much smaller, down to 0.16 ha. Clutch size varies geographically, altitudinally, with size of nest-cavity and quality of surrounding habitat, in Europe 7–13 eggs (clutches with in excess of 18 eggs generally the product of two females), in E of range generally 6–8 eggs; incubation by female, fed at nest by male, period 12–16 days; chicks fed by both parents, nesting period 16–23 days. Breeding success variable, influenced mostly by weather and predation, all following data from studies based on populations in nestboxes: in S England (Oxfordshire), 90–95% of young fledged in first three years, but success drastically reduced in following years through predation by weasel (*Mustela nivalis*); at second study site in S England, 33–77% of nests produced fledged young in different years and success affected mainly by grey squirrel (*Sciurus carolinensis*), weasels, rodents and Great Spotted Woodpecker (*Dendrocopos major*), and in some cases breeding pairs evicted by Tree Sparrows (*Passer montanus*); in Britain, success highest in gardens (86%), in Scots pine (*Pinus sylvestris*) plantations (71%) and in areas free from predation e.g. I of Rhum, in W Scotland (88%); nestling mortality rate affected by extent of rainfall, sudden drop in temperature, and availability of food, late-hatching young often poorly developed and suffer higher mortality. Juvenile mortality rate high in first three months of life, c. 70% between fledging and Nov. Breeds in first year. Estimated c. 75% of breeding pairs survive to following season (and some have remained together for 4 successive years); suburban pairs generally less productive, this attributed to lower nutritional value of available food. Maximum recorded longevity 12 years 4 months.

**Movements.** Mainly resident in C & S of range, partially migratory in N; also some seasonal altitudinal shifts. Evidence from ringing in Britain is that most movements are of 2–28 km (95% of recoveries within 10 km of ringing site, females moving farther than males), and none beyond 100 km; birds from higher altitudes of N Scotland make post-breeding descent to lower valleys. Elsewhere in Europe, N populations (juveniles and adult females) more regularly move S & W in Sept to late Oct to non-breeding grounds in NC Europe and S to around Mediterranean, arriving late Oct and present to mid-Mar in S Greece and mid-Nov to late Feb in Lebanon; rarely farther S, e.g. vagrant in NE Syria and Israel. Numbers recorded on passage at watchpoints vary annually, frequently in low thousands through passes in French Alps, and sometimes very large numbers in Baltic region; occasionally on irruption scale (when overall population at high level), as in autumn 1957, when considerable numbers moved from N & NE range into Baltic area and along S North Sea coast and many arrived on E & S coasts of Britain. Most movements involve first-years, and few adults involved. Longest distances recorded in ringing studies include movements from SE Baltic coast (Kaliningrad) to S Spain (2200 km WSW) and to Venice, in Italy (1260 km SSW), and from Germany to S Spain (1480 km SW).

**Status and Conservation.** Not globally threatened. Common to locally abundant, rare along N edge and in SE of range. Breeds occasionally outside normal limits of range, as e.g. in NE Syria (where otherwise a vagrant). European breeding population estimated at 16,500,000–23,000,000 pairs, most in Spain, British Is and Germany. Breeding densities vary according to habitat, provision of nestboxes and degree of competition from *Parus major*; densities generally highest in oak woodland, where can reach c. 250 pairs/km<sup>2</sup>, and lowest in conifer plantations. Range gradually extended N in 20th century, to S Finland from c. 1900, particularly since mid-1950s (when also increased in Netherlands), and in 1970s expanded into Norway and N Scotland. Population in N Jordan first discovered in 1893, but not seen again until 1984, and breeding first proved in 1990. Appears able successfully to withstand severe winter weather, suffering only some local or short-term fluctuations in numbers; provision of food at birdtables considered to account for considerable portion of winter sustenance enabling large numbers to survive in times of hard or severe weather.

## 53. Canary Blue Tit

### *Cyanistes teneriffae*

**French:** Mésange des Canaries      **German:** Kanarenmeise      **Spanish:** Herrerillo Canario  
**Other common names:** Tenerife Tit; African Blue Tit (when combined with races *ultramarinus* and *cyrenaicae* of *C. caeruleus*)

**Taxonomy.** *Parus Teneriffae* Lesson, 1831, Tenerife, Canary Islands.

Until recently present genus normally subsumed into ■ broad *Parus*, and many authors still prefer that treatment. Forms a superspecies with *C. caeruleus* and *C. cyanus*. Previously considered conspecific with former, but has isolated island range and differs in mitochondrial DNA; alternatively, races *ultramarinus* and *cyrenaicae* of *C. caeruleus* may be better included in present species; further research required. Four subspecies recognized.

#### **Subspecies and Distribution.**

- C. t. palmensis* (Meade-Waldo, 1889) – La Palma, in NW Canary Is.
- C. t. ombriosus* (Meade-Waldo, 1890) – El Hierro (SW Canaries).
- C. t. teneriffae* (Lesson, 1831) – La Gomera, Tenerife and Gran Canaria, in C Canary Is.
- C. t. degener* (E. J. O. Hartert, 1901) – Lanzarote and Fuerteventura, in E Canary Is.

**Descriptive notes.** 11–12 cm; c. 10 g. Small, sharp-billed, compact tit. Nominate race has forehead and supercilium to centre of nape white, crown deep glossy blue, becoming blackish on hindcrown;

to blackish-brown; bill dark slate to black, paler cutting edges; legs slaty blue to slate-grey. Sexes alike. Juvenile is as adult, but forehead, supercilium and centre of nape yellow, crown and upperparts greenish-blue, rump dull green, tail dull blue, upperwing-coverts and flight-feathers fringed bluish, face and underparts yellow (becoming whiter with age), duller or tinged greyish on breast and belly, usually lacks dark central line on breast. Races differ mainly in colour tones of plumage and prominence of markings: *palmensis* is duller than nominate, lacks gloss on black cap (sootier on female), has broad or prominent supercilium and rather broad blackish eyestripe, upperparts duller or greyer, sometimes tinged green on back and rump, tail narrowly tipped white, narrow white tips on greater upperwing-coverts forming short wingbar, tertiaries and secondaries broadly tipped white, breast and flanks yellow, becoming white on lower breast and belly, and ventral line irregularly dark or absent; *ombriosus* is very similar to nominate but slightly larger, has green on upper mantle, greyish to olive-green on scapulars, narrow greyish-white tips on greater coverts, and darker or richer yellow underparts with short or narrow blackish ventral line; *degener* has black crown, narrower white supercilium and narrower blackish-blue on side of neck to throatband, paler or greyer upperparts, broad white tips of greater coverts and fringes of tertiaries, underparts paler yellow, whiter or lighter yellow belly, blackish ventral line from throat to centre of upper belly. Voice. Song of nominate race a variable repetition of one note or series of notes, ■ powerful, musical “chi-chi-chirichi-chichi” and a less melodic “chi-iss-chi-chi” or “iss-chichichiuu”, also a lively “chivichi-chivichi” and a musical “chillu-chillu-chi”; alarm a loud, vibrant, scolding “cher-er-er-er-g”, sometimes introduced with shorter “chi” or “chi-chi-chivichi”. On La Palma, race *palmensis* voice unlike that of any of other races (and more like that of *Parus major*), song a distinctive “tsa-zachuz”, sometimes with stuttering “er-er-r” introduction, also gives nasal “chié-chié-chié-chié-chié” and “chiff-chichichi”; calls include jangling “tchee tchee” and high-pitched wheezing “see chippi chippi”, alarm a harsh or grating “tcher-tcher-cher-cher-cher”. Race *ombriosus* alarm call and song similar to those of nominate, but song more rapidly twittering and prolonged. Race *degener* sings a distinctive “chii-er-er chii-er-er chii-er-er”, and calls similar to those of both nominate and *ombriosus* but louder.

**Habitat.** On arid islands of Fuerteventura and Lanzarote, breeds mostly in low-lying mixed tamarisk-palm (*Tamarix-Phoenix*) scrub-woodland and well-developed vegetation in grassy areas; elsewhere in variety of wooded habitats, from laurel (Lauraceae) woodland, tree-heath, wooded gulleys (barrancos), euphorbia scrub and parks and gardens (particularly those with fruit trees) to montane pine (*Pinus*, especially *P. canariensis*) forests, to c. 1300 m on Gran Canaria and to 1800 m on Tenerife. On La Palma (*palmensis*) apparently restricted to pine forest, and only occasionally found in adjacent undergrowth or laurel.

**Food and Feeding.** Details not well known; diet possibly not significantly different from that of *C. caeruleus*, except that it may take a larger number of small butterflies (Lepidoptera), aphids (Aphidoidea) and small beetles (Coleoptera). Usually in pairs, solitary, or in small (possibly family) groups; tame and often approachable. Agile, and actively forages at all levels in trees and undergrowth; in non-breeding season forages mainly in palms; frequently hangs upside-down from slender branches and pine cones.

**Breeding.** Season Feb–Jul, possibly also Oct–Jan; usually breeds earlier at lower levels than in montane areas. Nest similar to that of *C. caeruleus*, usually consists of moss, pine needles, leaves and feathers, placed up to 3 m from ground in hole or crevice in tree, wall or rock face, or on ground; also utilizes nestboxes. Clutch 3–6 eggs. No other information.

#### **Movements.** Resident.

**Status and Conservation.** Not assessed. Common on islands of Tenerife and Gran Canaria; scarce or local on Fuerteventura and Lanzarote. Fuerteventura population estimated at 366–1718 individuals in 2001.

**Bibliography.** Bannerman (1963), Clarke (2006), Cramp & Perrins (1993), Échécopar & Hûe (1967), Fry *et al.* (2000), García-del-Rey & Cresswell (2006), Grant (1979), Hagemeijer & Blair (1997), Harrop & Quinn (1996), Hartert (1905), Kvist *et al.* (2005), Lack & Southern (1949), Salzburger *et al.* (2002), Svensson *et al.* (1999), Vaurie (1957a, 1959).

## 54. Azure Tit

### *Cyanistes cyanus*

**French:** Mésange azurée      **German:** Lasurmeise      **Spanish:** Herrerillo Azul  
**Other common names:** Yellow-breasted (Azure) Tit, Turkestan Tit (*carruthersi*, *flavipectus* and *berezowskii*); Pleske's Tit (hybrid form “*pleskii*”)

**Taxonomy.** *Parus cyanus* Pallas, 1770, River Volga, Russia.

Until recently present genus normally subsumed into a broad *Parus*, and many authors still prefer that treatment. Forms a superspecies with *C. caeruleus* and *C. teneriffae*. Hybridizes with former, mainly following years when it expands W in periodic irruptions (hybrids described as a separate taxon, *pleskii*). SC Asian races *carruthersi*, *flavipectus* and *berezowskii* frequently considered to represent a separate species, but *flavipectus* hybridizes with race *tianschanicus* where ranges meet in S Kyrgyzstan; hybridization, however, appears to be limited; further study required. In addition, geographical variation slight and mostly clinal; in particular, race *yenisenseis* intergrades both with *tianschanicus* and with *hyperhipphaeus*. Eight subspecies recognized.

#### **Subspecies and Distribution.**

- C. c. cyanus* (Pallas, 1770) – Belarus and W & C European Russia E to C Urals.
- C. c. hyperhipphaeus* Dementiev & Heptner, 1932 – SW Urals, SW Siberia and N Kazakhstan.
- C. c. yenisenseis* (Buturlin, 1911) – SC Siberia, Altai Mts and N Mongolia E to NE China (Nei Mongol, Manchuria) and Russian Far East.
- C. c. tianschanicus* Menzbier, 1884 – mountains of SE Kazakhstan and adjacent Kyrgyzstan (C & E Tien Shan) E to NW China (N & W Xinjiang).
- C. c. kotalensis* Portenko, 1954 – lowlands of SE Kazakhstan.
- C. c. carruthersi* (E. J. O. Hartert, 1917) – Kyrgyzstan and N Tajikistan (Alai Mts and W Pamirs).

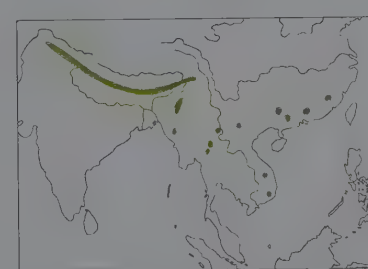

**Breeding.** Season Apr–Jun. Monogamous; territorial. Pair formation in late winter; display by male includes slow gliding flight from branch to branch, wing-shivering and calling, together with lengthy period of courtship feeding. Nest, built by female, mostly a cup of dry grasses, moss, plant down, animal fur and wool, placed 2–4 m from ground in hole or cavity in tree, sometimes among rocks or in hole in building, occasionally in pole (including those carrying urban streetlight). Clutch 7–11 eggs; incubation by female, period 13–14 days; chicks fed by both parents, fledging period c. 16 days. Of 76 eggs (12 clutches) in Kazakhstan study, 28 hatched and 26 hatchlings fledged; of

**Bibliography.** Ali & Ripley (1983), Cheng Tsohsin (1987), Cramp & Perrins (1993), Dementiev *et al.* (1954, 1970), Dolguшин *et al.* (1972), Étchécopar & Hûe (1983), Flint *et al.* (1984), Gill *et al.* (2005), Glutz von Blotzheim & Bauer (1993), Grimmelt *et al.* (1998), Hagemeijer & Blair (1997), Harrap & Quinn (1996), Harrison (1982), Hartert (1905), Hûe & Étchécopar (1970), Johansen (1944), Kovshar (1966), MacKinnon & Philipps (2000), McCarthy (2006), Meyer de Schauensee (1984), Rasmussen & Anderton (2005), Roberts (1992), Rogacheva (1992), Snow (1954a), Stenqvisten (1990), Svensson *et al.* (1999), Vaurie (1950, 1957a, 1959).

**Spanish:** Herrerillo Modesto

*S. m. klossi* Delacour & Jabouille, 1930 – SC Vietnam (Da Lat Plateau).

**Habitat.** Temperate montane and submontane forests, mostly oak (*Quercus*), rhododendron (*Rhododendron*) and mixed forests, at higher level in moss forest with epiphytes and scrub along treeline, but may also occur in willow (*Salix*) thickets and apricot (*Prunus armeniaca*) orchards; in S China also in spruce (*Picea*), fir (*Abies*) and rhododendron forests. Breeds in Himalayas at 2135–3600 m in W and 1980–3350 m in E, above 2350 m in NE Indian hills (Nagaland), and in S China usually at 1500–2800 m or locally higher (perhaps exceptionally to 4270 m in Yunnan), but down to c. 650 m in Fujian; in Myanmar at 2400–3000 m in W (on Mt Victoria) and at 1450–3350 m in N, in NW Thailand 1700–2590 m, and in Vietnam 2000–2800 m in N and 1500–2590 m in S. In non-breeding season also in deciduous and evergreen forests with rhododendron, bushes on hill,

sides and large gardens, often at lower elevations; recorded at 1200–2400 m in W Kashmir, 1500–2800 m in Nepal (exceptionally higher, to 4265 m), at 1525–3400 m in Bhutan and Arunachal Pradesh, and down to 900 m elsewhere in E Himalayas.

**Food and Feeding.** Diet largely unknown, but presumably includes small invertebrates and larvae, also some seeds. Usually solitary or in pairs or small groups in breeding season; in autumn and winter more often in mixed-species foraging flocks with other parids (especially *Parus monticolus*), Black-throated Tits (*Aegithalos concinnus*), various babblers (Timaliidae), Eurasian Treecreepers (*Certhia familiaris*), Goldcrests (*Regulus regulus*) and leaf-warblers (*Phylloscopus*). Fairly inconspicuous, and not often vocal. Forages mostly in middle and upper levels of forest trees and upper levels of taller bushes. Restless, flits about through foliage; agile movements and behaviour, including nervous wing-flicking, reminiscent of those of a leaf-warbler. Also clings acrobatically to twigs and leaves.

**Breeding.** Poorly known. Season at least Apr–May. Nest mostly a pad of moss, with animal hair or fur, placed up to 7 m from ground in natural tree hole or cavity with very narrow entrance (often a thin slit). Clutch 4–6 eggs; chicks fed by both parents, adults may become bold in defence of young. No further information.

**Movements.** Resident and short-distance altitudinal migrant. Post-breeding descent to lower levels in many parts of range.

**Status and Conservation.** Not globally threatened. Common or fairly common in much of range. Uncommon in W Himalayas (E to C Nepal) and uncommon in NW Thailand.

**Bibliography.** Ali & Ripley (1983), Cheng Tsohsin (1987), Etchécopar & Hüe (1983), Fleming (1973), Fleming *et al.* (1979), Gill *et al.* (2005), Grimmer *et al.* (1998), Harrap & Quinn (1996), Hartert (1905, 1921), Inskipp & Inskipp (1991), King *et al.* (1975), Lekagul & Round (1991), Löhrl (1988), MacKinnon & Philipps (2000), Meyer de Schauensee (1984), Rasmussen & Anderton (2005), Robson (2000, 2005a), Smythies (1986), Spierenburg (2005), Vaurie (1957b, 1959).

## Genus *MELANOCHLORA* Lesson, 1839

### 56. Sultan Tit

#### *Melanochlora sultanea*

**French:** Mésange sultane

**German:** Sultansmeise

**Spanish:** Carbonero Sultán

**Taxonomy.** *Parus sultaneus* Hodgson, 1837, Nepal.

Relationships uncertain; possibly closest to *Sylviparus*. With exception of isolated race *gayeti*, races intergrade widely. Four subspecies recognized.

#### **Subspecies and Distribution.**

*M. s. sultanea* (Hodgson, 1837) – E Himalayas from C Nepal to NE India (Arunachal Pradesh S to Manipur and Mizoram), Myanmar, N Thailand and S China (W & S Yunnan).

*M. s. flavocristata* (Lafresnaye, 1837) – C & S Thailand, Malay Peninsula and SE China (Hainan I); possibly also Sumatra.

*M. s. seorsa* Bangs, 1924 – N Indochina (S to C Laos) and SE China (Guangxi, Fujian).

*M. s. gayeti* Delacour & Jabouille, 1925 – SC Vietnam (C Annam).

**Descriptive notes.** 20–21 cm; 35–49 g. Largest member of family; strikingly black and yellow, with long bright yellow (or black) floppy crest, long and slightly graduated tail. Male nominate race has forehead, crown and crest bright sulphur-yellow; rest of head, upperparts, including wing and tail, and chin, throat and breast glossy greenish-black, some individuals with outer tail feathers narrowly tipped whitish; underparts below breast, including axillaries and underwing-coverts, bright yellow; iris brown to reddish-brown; bill black or bluish slate-grey; legs blue-grey, sometimes tinged greenish. Female is very like male, but slightly duller or sooty brown, and glossed greenish. Juvenile is as female but lacking gloss, has crest shorter and more rounded, narrow pale

yellow or whitish tips on greater coverts and occasionally primary coverts, underparts duller yellow, young male may show bluish gloss on upperparts from early age. Races differ little: *seorsa* is as nominate, but yellow areas of plumage slightly paler, and may have black shaft streaks in crest; *flavocristata* is as nominate but crest shorter, juvenile has dark shaft streaks in crest and occasionally white tips on tertials and secondaries; *gayeti* is distinctive, has forehead, crown and crest black (not yellow), black upperparts only lightly glossed bluish, female browner and with generally duller greenish gloss. Voice. Generally fairly vocal.

Calls include flat but stony or rattling “chi-dip, tri-trip” or similar metallic “tji-jup”, also a harsh and explosive “krssh-krssh” or slightly longer “krsshup-krsshup”, and a faster and shrill whistled “tria-tria-tria” or “tcheery-tcheery-tcheery”, usually with rising pitch, or harsher “squear-squear-squear”; also utters short and squeaky “whit” or “quit” and louder and ringing “weet”, “vheet” or “zeent-zeent”. Song a series of up to 5 loud, clear and ringing “chew” or “kree” or “piu” whistles, frequently repeated, also as more squeaky “pree-yit, pree-yit, pree-yit”, strident but downslurred “fyu-fyu-fyu-fyu” and rapid, shrill “chit-ter-der chit-ter-der”, likewise repeated several times.

**Habitat.** Edges of lowland and submontane (also lower montane) deciduous, mixed deciduous and evergreen forests, also light forest with bamboo, secondary growth, scrub and edges of cultivation. Breeds mostly below 1220 m in SC China, but occurs to 1370 m in Nepal, 1900 m in Sikkim, 1600 m in Arunachal Pradesh, at 200–2000 m in Bhutan, to 1680 m in N Myanmar, 1000 m in Thailand and 1220 m in Malay Peninsula (but to 1500 m in Cameron Highlands); in C Vietnam, rare below 200 m and frequent at c. 1400 m.

**Food and Feeding.** Diet chiefly small invertebrates and larvae, principally grasshoppers and crickets (Orthoptera), mantises (Mantidae) and spiders (Araneae); also some fruit, mainly berries, also seeds. Usually in pairs and in family groups of up to twelve individuals; also in mixed-species foraging flocks with sibilas and other small babblers (Timaliidae). Forages usually in foliage of upper and canopy levels of trees, when often inconspicuous, but also sits in the open on tops of trees; occasionally also in middle levels or tops of taller undergrowth and bamboo. Active and somewhat acrobatic in foraging motions, but rather more lethargic than other parids, and movements often rather stiff. Flits between branches, and agile when in flight through forest, but in open areas flight fairly fast and bounding. Gleans items from substrate; also hovers briefly on outside of foliage, and occasionally catches insects in flight.

**Breeding.** Poorly known. Season Mar–Jul. Few nests described, composed mostly of grass, green moss, plant down and fibres, leaves and animal hair, placed up to 15 m above ground in hole, crevice or cavity in tree. Clutch 5–7 eggs. No other information.

**Movements.** Resident, with some short-distance dispersal; in NE India, non-breeding visitor in foothills in Nameri National Park, in W Assam.

**Status and Conservation.** Not globally threatened. Fairly common in Bhutan and E Himalayas, and rare in W Himalayas, Nepal and Sikkim; local and uncommon in S China, and on Hainan recorded from only four forest sites; locally common to uncommon in Thailand, and fairly common in C Vietnam; uncommon or scarce throughout most of Myanmar, but locally common in Kachin Hills. Formerly occurred in Bangladesh, but no recent records. Status in Sumatra uncertain, although race *flavocristata* apparently described from there; possibly a rare resident, but known only from a single record of a small party in forest canopy at 100 m in Utara in 1938; 19th-century reports from Sumatra not verifiable, as specimens apparently lost. Population decline recorded in W Himalayas and N India considered directly attributable to habitat destruction.

**Bibliography.** Ali & Ripley (1983), Barua & Sharma (2005), Cheng Tsohsin (1987), Etchécopar & Hüe (1983), Fleming *et al.* (1979), Gill *et al.* (2005), Grimmer *et al.* (1998), Harrap & Quinn (1996), Jeyarajasingam & Pearson (1999), King *et al.* (1975), Lekagul & Round (1991), MacKinnon & Philipps (1993, 2000), van Marle & Voous (1988), Medway & Wells (1976), Meyer de Schauensee (1984), Pui Lok *et al.* (2005), Rasmussen & Anderton (2005), Robson (2000, 2005a), Smythies (1986), Spierenburg (2005), Stuart Baker (1932).

## SUMMARY OF VOLUME 12

PICATHARTIDAE (Picathartes)  
TIMALIIDAE (Babblers)  
PARADOXORNITHIDAE (Parrotbills)  
POMATOSTOMIDAE (Australasian Babblers)  
ORTHONYCHIDAE (Logrunners)  
EUPETIDAE (Jewel-babblers and allies)  
PACHYCEPHALIDAE (Whistlers)  
PETROICIDAE (Australasian Robins)  
MALURIDAE (Fairy-wrens)  
DASYORNITHIDAE (Bristlebirds)  
ACANTHIZIDAE (Thornbills)  
EPHIANURIDAE (Australian Chats)  
NEOSITTIDAE (Sittellas)  
CLIMACTERIDAE (Australasian Treecreepers)  
PARIDAE ( Tits and Chickadees)

## TECHNICAL DETAILS

- 310 × 240 mm
- 816 pages
- 56 colour plates
- 436 photographs
- 638 distribution maps
- c. 4000 bibliographical references
